The obligate parasite *A. conchicola* (Trematoda: Aspidogastridae) is widespread and occurs in all species of the Unionidae family. It has a direct life cycle, which allows it to successfully and quickly enter the symbiocenosis of a species new to the ecosystem. The parasite can complete its life cycle without leaving the mollusk. Adults mature in the pericardial cavity and kidneys, in which they remain to live. In most cases, there were no lesions associated with the vital activity of *A. conchicola*. However, it can damage host tissue through suction and feeding. Local cellular changes are possible, such as necrosis, metaplasia. Mollusks can encapsulate aspidogasters (encapsulation reaction or granuloma) if they invade tissues [28, 29].

In the examined mollusks, the level of invasion with aspidogasters is low. Thus, the prevalence of these parasites is 13,7%, and the intensity of invasion is 2 specimens. The abundance index is only 0,3 ind. Aspidogasters were found in the pericardium in 71,4% of the invaded individuals and in the kidney – in 42,9%. Host age does not significantly affect helminth infection. So, individuals of almost all age categories from 3 to 7 years old were infected. However, 2-year-olds were not infected with *A. conchicola*.

Among the facultative symbionts, we identified the two-eyed flat leech *H. stagnalis* (Clitellata: Glossiphoniidae), which was localized in the mantle cavity of *S. woodiana*. Its body length was 6–10 mm, width was 1–3 mm. The body is short, wide, and flattened dorsally. The front half of the body can stretch strongly. The body is grayish-white, with a large number of brown spots on the dorsal side. A distinctive feature of the species is a brown lenticular plate on the back between the 12th and 13th rings, which is visible through a microscope. Also, this leech has only one pair of eyes that are quite large. The prevalence of this symbiont was 9,8%. The two-eyed flat leech belongs to the organisms of macrozoobenthos, as it lives in stagnant and flowing water bodies on plants and stones, to which it attaches with the help of suckers. It prefers small stagnant overgrown reservoirs. It is α-mesosaprobe. The two-eyed flat leech is very mobile and can swim.

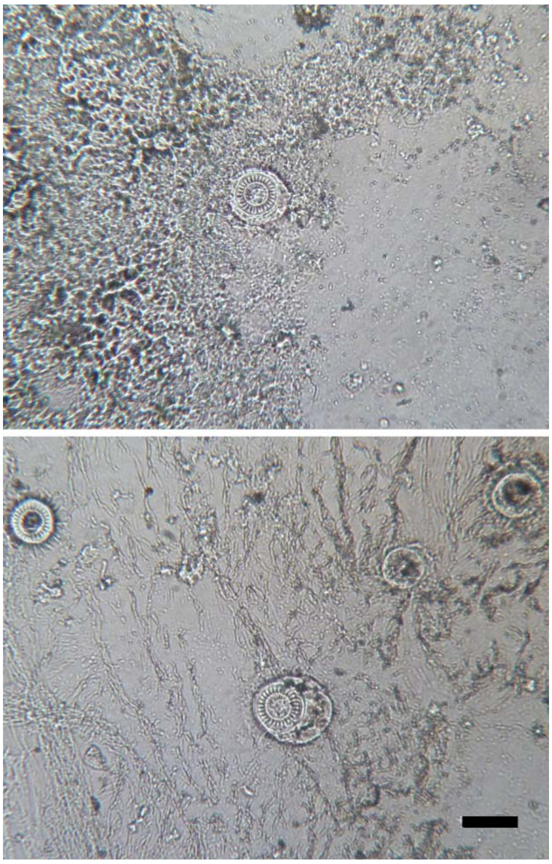

Fig. 3. *Trichodina* sp. found in the mantle cavity of *S. woodiana* (×200). Scale bar: 200 μm.

We found larvae of *Chironomus* sp. (Insecta; Chironomidae) between the external gills and the mantle. The prevalence in the studied mollusks is insignificant – 3,9%. The intensity of symbiont is minimal – 1 specimen per individual. Taking into account the low values of the prevalence and intensity of colonization of the Chinese pond mussels by these organisms, it is possible that they accidentally entered their mantle cavity. However, getting into the mantle cavity, they can exist in association with the mollusk for a long time (this assumption is supported by the fact that the identified above-mentioned free-living organisms were alive and active at the time of the dissection).

So, 45.1% of the studied individuals of *S. woodiana* from the pond in Romanivka village was inhabited by symbionts. Mixed invasions were observed in 17,4% of individuals. Other mollusks were inhabited only by representatives of one taxonomic group.

As for the prevalence of symbionts, depending on the age of the mollusk, in 2-year-old specimens of the Chinese pond mussel this indicator is the smallest (12,5%)

among the age groups, and only one symbiont was found in them – the ciliate *Conchophthirus* sp. (Fig. 4). Almost all symbionts described in the article are found in 3-year-old mollusks and their prevalence in this age group is 53,3%. Only the larvae of *Chironomus* sp. identified in 4-year-old and older individuals. The prevalence of symbionts in 4-year-old *S. woodiana* and older age groups is 42,8–66,5%.

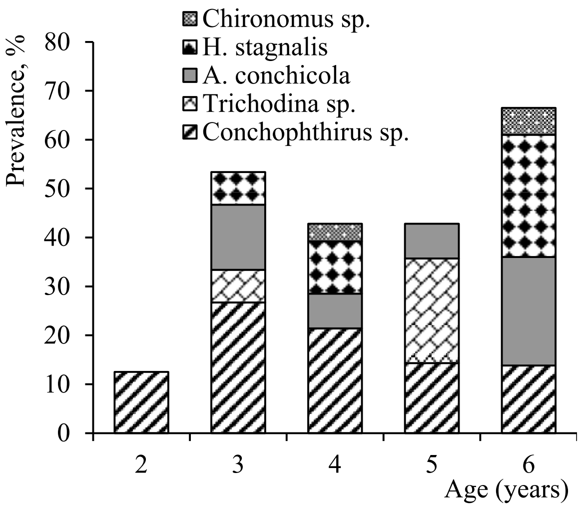

Fig. 4. Prevalence of symbionts in *S. woodiana.*

The large bivalve mollusks *S. woodiana* are an attractive habitat for various freshwater symbionts. This is possible due to the biological characteristics of the species (a large body size and significant biomass in the ecosystem) and its ecological features (resistance to water pollution and oxygen deficiency) [30]. Such hosts provide the best opportunities for symbionts for nutrition, mobility, protection from anxiety, and reduce the risk of predation.

4 Conclusions

It was determined that even significant climatic differences between the invasive part of areas (a reservoir with a natural temperature regime in northern Ukraine) and the native part do not create a barrier for the spread of *S. woodiana*. The low water temperature does not limit the spread of the Chinese pond mussel, which indicates the significant ecological plasticity of this species and the ability to survive and spread in conditions of sufficiently low temperatures. The high percentage of females with gill pregnancy indicates that the development of mollusk larvae under new conditions is close to normal. The presence of a large number of young individuals in the age structure of the population indicates the active reproduction of local populations.

The Chinese pond mussel easily conquers new habitats, where it enters into a variety of biocenotic relationships with local species of freshwater fauna, thereby confirming the stability of its existence in new conditions. Our results show that *S. woodiana*, a species alien to Ukraine, can be inhabited by various groups of symbionts living in Europe. Among the local symbionts in mollusks from a pond in Romanivka village, we noted ciliates *Conchophthirus* sp., two-eyed flat leech *H. stagnalis*, larvae *Chironomus* sp. that enter commensalism with mollusks, *Trichodina* sp. and *A. conchicola*, which are parasites of the mollusk. Also, the Chinese pond mussel enters into a relationship of interspecific competition (like any invader species) with local mollusks of the Unionidae family, significantly reducing their numbers. That is, *S. woodiana* can, directly and indirectly, influence the natural biota of the aquatic habitat in the invasive part of the range.

Further spread of *S. woodiana* to the cold regions of Ukraine and the formation of new populations in the already developed regions should be expected.

In the future, we consider it expedient to monitor the state of the *S. woodiana* population from the pond in Romanivka village, to study the annual changes in the age and sex structure, the features of the growth rate of the shell of mollusks and the influence of the invader on the native species of unionid mollusks.

Abstract. The neutralization of toxic mine rocks with additional of soil and loess like loam mass leads to a significant decreasing of salts migration at the contact zone. The mathematical model was working out follow general principle where mine rock is pollution source, but soil and loess like loam take place as volumetric filter for water-soluble salts. MathCAD file with commands for solving the problem forecasting the process of vertical salinization of reclaimed minelands was developed. The prospect for the numerical model using up to the most accepted range of values with experimental data shown. The irrigation of reclaimed minelands in the Western Donbass possible in the case of the dilution of the mine waters of aquifers with the Samara river water.

1 Introduction

Rainfall, evaporation, rock weathering, saltwater intrusion, or chemical contamination can cause the salt source for soil salinization in abandoned and reclaimed minelands [1]. Modelling is a suitable alternative technique that saves time and cost for the environment monitoring [2]. Meantime the performance of the models should base on long-term monitoring data. The fate of chemical substances in the soil is complex and dynamic, depending on such factors as clay level, soil pH, hydraulic conductivity, structure, and many others [3]. From the general convection-dispersion function describing solute transport in porous media, several numerical and analytical models have evolved [4, 5]. These include the finite difference approaches. HYDRUS, SALTMOD, PESTFADE, UNSATCHEM, SODIC and SWAP have been widely used as seasonal models to consider the interaction between soil-water and water-soluble salts [6-8]. HYDRUS-2D demonstrates the relevance of numerical modelling in evaluating the water and salt dynamics under drip irrigated horticultural trees [9]. DRAINMOD-S was useful either for the design of a new drainage system and long-term impacts assessment on the groundwater table and soil salinity [10]. All hydrogeological processes: filtration, mass transfer and moisture transfer are those that have a limit and steady state. Pessimistic options have prospects. They calculate theoretically and prevent in advance [11]. Field experiments established 30-40 years ago in reclamation stations in areas affected by mine works require additional research to justify the choice of a mitigation technology or rock deposits replacement in a way that would guarantee the least negative consequences for the environment. It is necessary to introduce a procedure of environmental impact assessment (EIA) for the recommended technologies of reclamation of disturbed lands [12]. The EIA methodology involves the identification of impacts, the choice of mitigation technology, following modeling and forecasting its positive effect.The main objective of our research was to substantiate decisions to create favorable ecological and reclamation conditions on reclaimed mine dumps in the Western Donbass.

2 Materials and methods

The data on salinization of two land reclamation profiles in 1987, 1995, 2003, 2008 and 2018 obtained in the conditions of the Pavlograd experimental station of the DSAEU. The station founded in 1976 in the floodplain of the Samara River in order to examine the best restoration measures. Typical abandoned site shown in the figure 1.

Other example connected with intention to create dachas for mining workers in Pavlogradsky district just in reclaimed minelands (Fig.2). The scheme for reclamation of disturbed land based on the study of the effectiveness of capping the mine dumps with different layers of black-soil mass (chernozem) both with and without a shielding layer of loess - like loam. The following models of artificial land reclamation profiles were used to look into the peculiarity of upward migration of toxic salts from the mine dumps: 1 Mine rock (MR) + 50 cm of the top black soil (50BS); 2. MR + 50 cm of the loess-like loam (50LLL) + 50BS. Soil and rock samples taken along both

* Corresponding author: kharytonov.m.m@dsau.dp.ua

profiles, mixed thoroughly, air-dried and sieved through a 2-mm diameter stainless steel screen.

Fig. 1. Abandoned mining site in Western Donbass.

Fig. 2. Small dacha in reclaimed minelands in Western Donbass.

Soil pH and EC measured using a soil-to-water ratio of 1:1. pH and EC distribution in two land reclamation profiles are shown in fig 3.

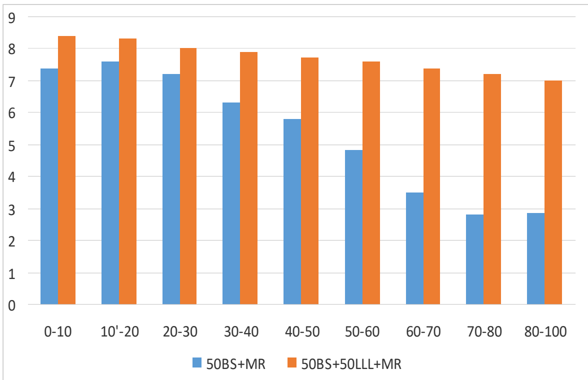

Fig. 3. pH distribution in two artificial profiles.

The differences in pH and EC profile distribution between two profiles demonstrate the negative impact of underlying toxic mining rocks caused with weathering in space and time. The applied model of the moisture-salt transfer process based on the theory of physicochemical hydrodynamics of porous soils. Mass transfer processes are described by differential equations of motion and conservation of matter mass of the second order in partial derivatives of elliptic and parabolic types according to this theory. One - dimensional versions of these equations used for solving practical problems. This process describe by the equation of movement and of mass of matter mass keeping:

$$D\frac{\partial^2 c}{\partial x^2} - V\frac{\partial c}{\partial x} = m_0\frac{\partial c}{\partial t}, \qquad (1)$$

where C – soil salinity, %; D – hydrodispersion coefficient; x – spatial coordinate; t – time; V – infiltration rate, m/day; m_0 – topsoil moisture, %. This is due to the fact of the salt transfer in the aeration zone takes place mainly in the vertical direction.

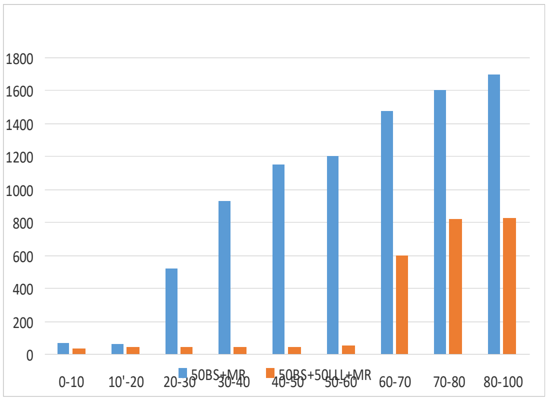

Fig. 4. EC distribution in two artificial profiles, units.

A special MathCAD file created to predict the process of vertical salinization of the topsoil. Commands to solve the simulation problem to this file written. It is enough to substitute the original data into this file. The program itself will calculate the result. Constants and procedures are on the first two sheets of the MathCAD document. They changed under the conditions of introduction of new initial parameters. It is necessary to indicate the depth of the artificial soil profile, modeling time, step in space and time correctly. The operator: = to set the value of the variable used. The name of the variable to the left of it written. Variable value: *upper_border*:=0 and *lower_border*:= 1 is written on the right. Sign (dot) used to separate integer and fractional part in number. Variables *upper_border* and *lower_border* used to establish border boundaries. Value *upper_border* always set to zero. The dimensions along plot are in meters. Variable *dx* used to change the size of the soil layer. The size of the soil layer is set as 10 cm in the section of global constants. This value changed as follows: *dx: =0.1* when the size of the reclamation layer differs. The variable *t* to change the simulation time used. Simulation time in days is measured. The number of year's t: = translated into the number of days. The number of simulation steps (periods into which the simulation time is divided) must also be set. The number of steps from 10 to 16 recommended. It is possible to use other values as well. The variable steps: = 32 used to set the number of steps. The variable *n* used to find the number of steps in space. It calculated automatically by the command:

$$n := \frac{(lower\_border - upper\_border)}{dx}.$$

 https://doi.org/10.1051/e3sconf/202128006007

This command can not be deleted. The most important step in future modeling is to enter the initial salinity values. The character C denotes salinity. It inserted in a slightly different way than all other data since salinity is not one value. Character *C* selected in toolbar in the menu after entering C: = Item "Insert - Matrix". It is necessary to select the number of horizontal and vertical values in the window that appears. The number of values horizontally is always set to 1. A step plus one vertically should indicate the height of the soil profile. A blank for entering salinity data of the soil profile will appear on the screen. The results are displayed on the screen using the command res= after that. Name *res* used in the previous command (or  - on the toolbar) used to construct the surface of the results Command "Insert - Graph – Surface Plot". 3D a surface with three coordinates (y (*C*) is the salinity of the soil, z (t) is time, x is the spatial coordinate, dm) appears on the screen.

3 Results

The choice of measure to neutralize potentially toxic rocks related to the ratio of precipitation and evaporation at each site. Evaporation is a negative component of the water balance. Evaporation involves a complex water vapor between the ground surface and the atmosphere. Its value depends on the depth of groundwater, lithological composition of the rocks, vegetation cover and complex climatic factors. The maximum evaporation for the Dnipropetrovsk province is 800 – 820mm [13]. The ratio between precipitation and evaporation is 0.5. The rate of vertical moisture - salt transfer preliminarily estimated by the balance method according to the formula (2):

$$\boldsymbol{V} = \frac{\boldsymbol{P-(E-W)}}{\boldsymbol{1000T}}, \qquad (2)$$

where P - precipitation, mm, E – evaporation rate, mm, W – water accumulation (moisture removal with plant biomass), T – grass vegetation period, days. The coefficient of water consumption (W) varied depending on the type of plant – from 450 to 550 m^3/t. In subsequent calculations, the formula used to calculate the hydrodispersion coefficient (3):

$$D = V \cdot \frac{x}{2 \cdot ln\left(\frac{C_2}{C_1}\right)}, \qquad (3)$$

where V – velocity of vertical moisture transfer, m/day; C_2 – salinity at a point with the coordinate of the mine dump (x, m), C_1 – mineralization depending on the surface of the dump. The mathematical model was refined in the second stage by solving multivariate forecast problems to the best coincidence of the calculated values with the experimental data. The use of such an approach in the mathematical model of vertical salt transfer along profile of the dump of mine rocks allowed taking into account the surface runoff. Equation (1) proved for this to the form of boundary differences:

$$D\left(\frac{C_{i+1}^{\tau+1}-2C_i^{\tau+1}+C_{i-1}^{\tau+1}}{(\Delta x)^2}\right) - V\frac{C_{i+1}^{\tau+1}-C_i^{\tau}}{\Delta x} = m\frac{C_i^{\tau+1}-C_i^{\tau}}{\Delta t} \qquad (4)$$

where τ – time grid point number; i – spatial grid point number. The boundary condition of the 3rd kind Dankwerts - Brenner [14] was given at the upper bound:

$$[C(0,t) - C_n] \cdot V = D\frac{\partial C(0,t)}{\partial x} \qquad (5)$$

Boundary condition of the 1st kind (C_0 = const) was set at the lower limit. Consider more carefully the boundary condition at the upper bound. Write the formula (5) in another form:

$$(V_2 - V_1)(C_n - C_0) = D\frac{\partial C}{\partial x} \qquad (6)$$

After giving the equation in the form of finite differences and opening the brackets in the left part of the formula we get the following formula:

$$V_2C_n - V_2C_0 - V_1C_n - V_1C_0 = D\frac{C_0 - C_1}{\Delta x}. \qquad (7)$$

We proceeded from the position that the third component in the left part was equal to zero, because the evaporation of salts from the soil surface under natural conditions does not occur. The boundary condition in this case takes the following form:

$$DC_0 + \Delta x V_2 C_0 + \Delta x \cdot V_1 \cdot C_0 = D \cdot C_1 + \Delta x \cdot V_2 \cdot C_n, \qquad (8)$$

where V_1 – ascending flow rate of the substance, m / day;
V_2 –downward flow rate of the substance, m / day;
C_p –mineralization of precipitation, %
C_0 –salinity on the top soil, %;
Δx –step along the spatial coordinate, m

The vertical transfer rate was calculated as the speed difference V_2-V_1 taking in account that this boundary pre-condition is used. The salinity forecast scenarios was made for the two- and three layers reclamation profiles during a period of three decades (Fig. 5 and 6).

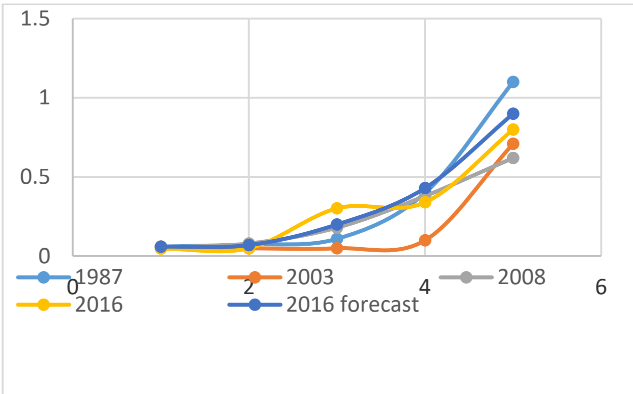

Fig. 5. Estimation and forecast of salinization of the two-layers profiles, %.

The results of the forecasts for one of the two recommended reclamation profiles are in good agreement with the data of experimental observations for 1987, 2003, 2008 and 2016. The analysis of changes in the content of water-soluble salts at the contact of the lower layer of the soil with the mine rock in the trial MR + 50cm Black Soil indicates a slow decrease in the soil mineralization. The tendency of slow increase in salinization of the upper soil layers of the artificial reclaimed profile is recorded. At the same time, the comparison of soil salinization data in the options MR + 50cm Black soil and MR+ 50 cm Loess Like Loam + 50 cm Black Soil testifies in favor of the three - layer reclamation profile. The same conclusion made after trend analyse analysis of water-soluble salts vertical migration in technogenic edaphotops of reclaimed mine dumps [15].

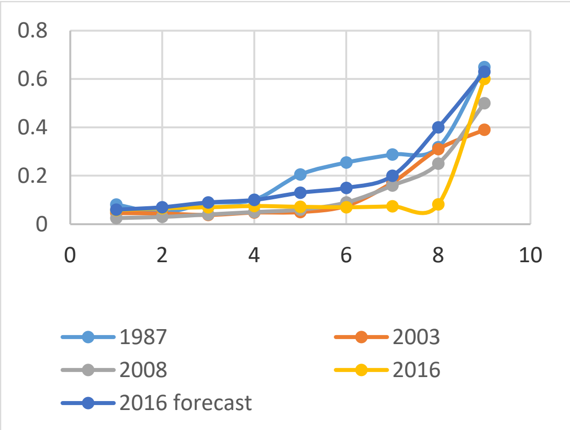

Fig. 6. Estimation and forecast of salinization of the three layers profiles, %.

It is obviously also that there is a certain pattern of growth of the content of soluble salts in the layers in the chernozem, which was dumped on the mine rock, approaching the mine rock. The topsoil looks like a volumetric filter of soluble salts migrating from the lower layer of mine rock. Thus, the salt concentration on the surface will be lower the larger the soil layer. This observation led to the theoretical assumption that the mine rock is a source of salinization, and black soil as volumetric filter for salts migration and absorption by the soil. Therefore, the obtained experimental data allowed building a mathematical model of the generalized dependence of the content of soluble salts in the layer of black soil of different heights, poured on top of the mine rock. The database grouped by the distance of a certain layer, starting from the mine rock, and the corresponding values are plotted on a scatter plot (Fig.7).

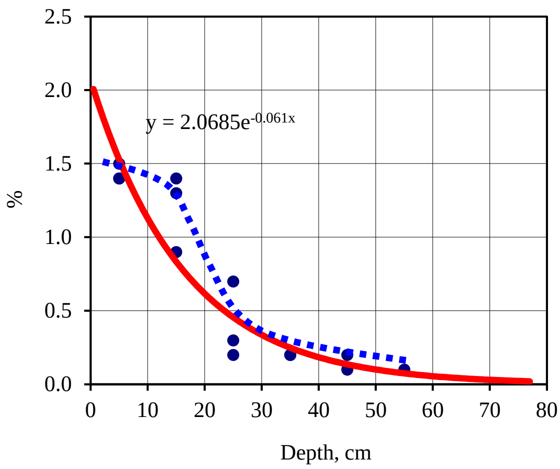

Fig. 7. Dependence of the content of soluble salts on the thickness of the soil layer.

The trend in the form of an exponent represent by a solid line. The possible real dependence presented by a dotted line. The smoothing of the discrete series of values performed by the exponent described above-mentioned assumption. Quantitatively, the molecular diffusion of substances described by first and second laws of the Fick. Under the above conditions, the differential equation of mass transfer of pollutants looks like the equation of diffusion of matter everywhere per unit area (Fick's first law):

$$j = -D\frac{dC}{dx}, \text{ mg/cm}^2, \tag{9}$$

where C is the mass concentration of the flow of the transferred substance through the selected plane, mg / m^3; x is the current coordinate in the direction of flow, m; D is the diffusion coefficient, m^2 / s.

Therefore, according to the law of diffusion, the salts drift into the region with a lower concentration. This process written in the form of an equation for a steady state in the soil in which there is no time factor, namely:

$$\frac{dC}{dl} = -k \cdot C, \tag{10}$$

where C is the concentration of the migrating substance, mg / m^3 or%; l is the thickness of the layer of loose soil), m (cm); k is the filtration coefficient of dissolved salts in the soil, m^{-1}. Analytical solution of equation (10) with initial conditions, for (salt concentration at the boundary of the soil with the mine rock) has a general form

$$C = C_0\, exp(-k \cdot l). \tag{11}$$

Since the nature of salt migration influenced by various factors, the real dependence of the salt content describe by a second-order differential filtration equation. For practical conditions, in our opinion, it is sufficient to apply a simplified version of the exponential dependence, which represent in an approximate normalized form (12):

$$C = C_0\, exp(-0{,}05 \cdot l), \tag{12}$$

where l - the salt content in the topsoil adjacent to the surface of the mine dump or at a depth selected for the initial level of reference in the soil, %. According to the properties of the exponent, a decrease in the salinity of chernozem in *e* times, ie 2.7 times, will be observed at a layer thickness of 20 cm. Almost zero concentration will decrease at a layer thickness of black soil at (3-4) 1 / k , i.e. 3-4 times larger, namely - 60-80 cm.

Verification of this model and its subsequent identification for chernozem was performed three times on the basis of experimental data obtained in the Pavlograd reclamation hospital every eight years. The results of the distribution of salt content in soil samples taken in the reclaimed profiles of the two-layer variant are presented in Figure 8.

As we can see, the content of soluble salts in chernozem depends not only on the soil layer, but also on the period from the beginning of reclamation. In this case, over time, there is an increase in the maximum concentration of salts (curve 2 in Fig. 8), coming from the lower layers of the rock to the chernozem, and then, over the years - a gradual decrease (curve 3).

The calculations showed that in real conditions, when the mode and duration of salinization are unknown, it is possible to use a model that takes into account all available experimental data.

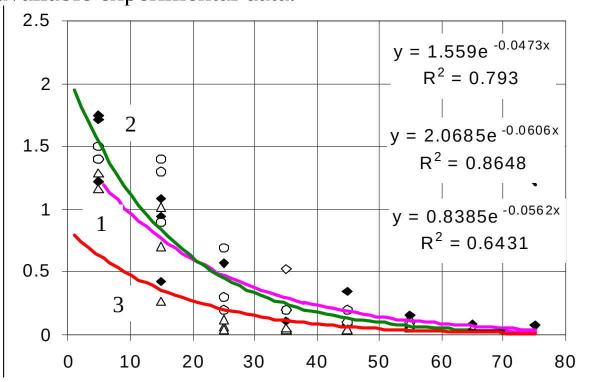

Fig. 8. Profile distribution of salt content (y,%) depending on the thickness of the layer (x, cm) of black soil.

This dependence represented in the form (11), where the coefficient k is approximately in the range of 0.05-0.06 m – 1, and the value will depend on the level of the initial salt concentration in the rock. The introduction of a 50 cm layer of loess-like loam in the option 50BS + 50LLL + MR led to a significant decreasing of the chemical weathering process of underlying mining rocks (Fig. 9).

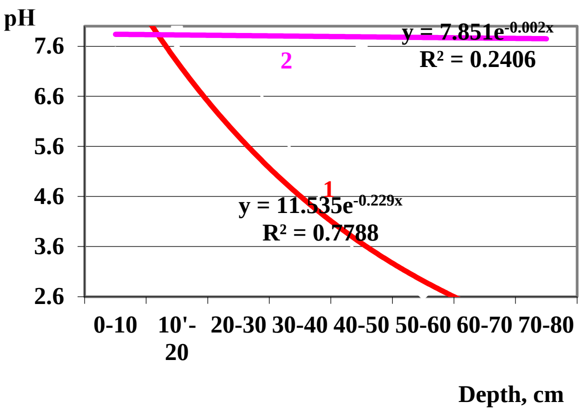

Fig. 9. Modeling of pH distribution along two land reclamation profiles: 1-50BS+MR; 2-50BS+50LLL+MR.

Therefore, pH stabilization in the trial 50BS + 50LLL + MR is possible in the range of 7.6-7.7. Estimation of quality of waste mine waters of the Western Donbass has shown that a certain part of weakly mineralized waters can be suitable for irrigation under conditions of dilution of mine water of artificial ponds by water of the Samara river (Fig. 10).

The results of the calculation of salt migration for the trial with dilution shown in Fig. 11.

The forecast of the salt regime of the reclaimed mine dump with systematic irrigation in the option with water dilution of the irrigation source up to 1.6 g / dm^3 was performed for a period of 5, 10, 20 years in the steady state for the initial salinity of 0.6 and 0.8%. The process characterized by a constant content of salts of the topsoil with slow salinization of the upper part of the mine rock heap. The calculation of the required amount of gypsum as an ameliorant performed by the formula:

$$\ldots\ldots\ldots\ldots \quad R = E \cdot \left[Ca^{++} - C^{++}{}_f\right] \cdot N, \ldots \qquad (13)$$

where R – ameliorant dose, t / ha; E – the equivalent of ameliorant, which is equal to 1 mg - eq Ca^{++}; Ca^{++}– the amount of Ca, which is equal to 43.4mg-eqv/dm^3; N – irrigation rate, thousand m^3 / ha. The dose of gypsum for case study of the Samara river as a source for topsoil irrigation is following:

$$R = E \cdot \left[Ca^{++} - C^{++}{}_f\right] \cdot N =$$
$$8.6 \cdot [16.6 - 11.1)] \cdot 1000 = 0.5 ton / ha$$

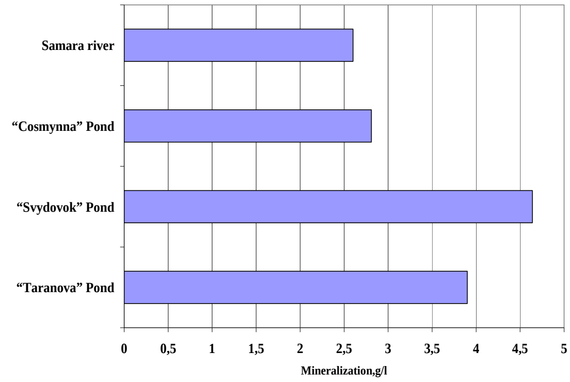

Fig. 10. Water mineralization in river and mine ponds.

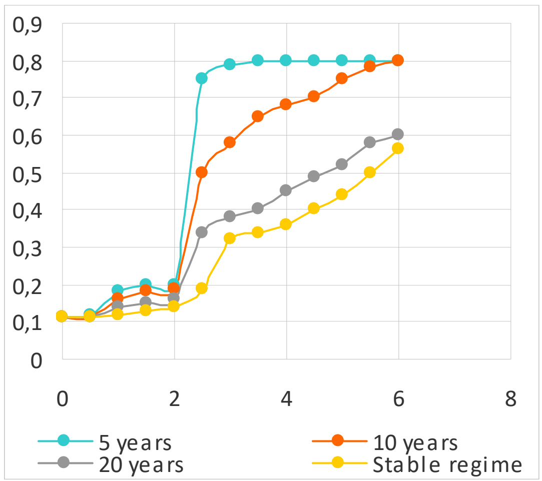

Fig. 11. Dynamics of salt transfer on a reclaimed mine dump with irrigation, %.

The implementation of the environmental protection measures recommended for production took place as follows. On the one hand, some reclaimed territories transferred to the balance of private farms in Pavlograd district. At the same time, a certain share of reclaimed areas given to several horticultural societies with a total area of more than 100 hectares. All of them are located in the floodplain of the Samara River.

The calculations proved that in any case of reclaimed mine dump salinization of the top soil is inevitable. It is necessary to create a flushing mode to prevent it. Irrigation carried out with the minimum norms.

4 Discussion

The main problem in identifying the optimal scheme of land reclamation in the coal mining regions is the prevention man-made pollution of artificial landscapes [16, 17]. Given the trend of transition from land use as arable land to the state of natural meadows, the latter type of nature management of reclaimed land in the Western Donbass seems less risky for the development of soils vertical salinization.

The solution of the migration problem for reclaimed mine dumps in the steady state with the maximum values of the initial salinity of dump rocks (0.8-1.0%) should be considered as an extreme negative option, leading to intensive accumulation of salts in the soil.

Analysis of vertical migration of salts with the depth of the reclaimed profile showed that none of the options with a top layer of chernozem 30, 50 and 70 cm did not provide complete stabilization of the distribution of pH and water-soluble salts. Predictive calculations based on the theory of migration proved the possibility of salinization of the topsoil without irrigation due to the pulling of salts by the upward flow of moisture.

Therefore, stable and favorable ecological and reclamation conditions created with the use of systematic irrigation. Three types of irrigation regimes used in different natural and climatic zones of Ukraine: compensatory, evaporating and washing [11]. Conditions for the application of compensation and evaporation regimes are more typical for the Central Donbass, where mine rocks are not saline.

The flushing regime of irrigation of reclaimed dumps is more suitable, as they are everywhere to varying degrees saline. Irrigation by brackish water is a possible solution to alleviate freshwater shortages [18]. The simulated results were helpful to provide a basis for assessing the environmental effect under long-term brackish water irrigation.

During long term, salts leaching under the effects of rainfall can contaminate groundwater [19-20]. On the other hand, the salinization phenomenon in the topsoil can be cyclic, and the effect of salinity on crops attenuated with proper management that involves appropriate irrigation for salt leaching [21-23]. This risk reduces in the case of special irrigation strategy. This requires lower irrigation doses and the use of a drip irrigation system associated with proper management practices such as increasing irrigation frequency.

5 Conclusion

Slow salinization of the topsoil described for the three-layer reclamation profile. The introduction of a carbonate-containing layer of loess like loam is a reliable geochemical barrier to counteract the process of vertical migration of water-soluble salts from the surface of the mine dump. Creating a leaching regime with a downward flow of moisture is a guarantee to prevent the development of the process of soil salinization. In this case, irrigation carried out with minimum standards. Irrigation with ponds-accumulators water diluted by water of the Samara River can be tolerable to the grass and induces a low topsoil salinization risk in the artificial land reclamation profile**.** Given the trend of transition from land use as agricultural land to the state of natural meadows and plantations for second generation energy crops cultivation, the latter type of nature use of reclaimed land in the Western Donbass is less risky.

Removal of Cr(VI) from wastewater by silver-loaded natural clinoptilolite

Marinela Panayotova

University of Mining and Geology, Dept. of Chemistry, Sofia 1700, Bulgaria

Abstract. Presence of hexavalent chromium, Cr(VI), in water is an important environmental and human health problem. Natural zeolites are widely accepted as non-expensive adsorbents for sustainable remediation, however they are not effective in removing metals in anionic form. The paper presents study on use of silver (Ag) modified natural clinoptilolite to immobilize Cr(VI) ions from model and real neutral to slightly alkaline wastewater. Increasing the initial pollutant concentration increases the removed amount (80 % removal from model wastewater in 45 min at initial concentration of 30 mg Cr(VI)/L). The pseudo-second order kinetic equation best describes the Cr(VI) immobilization by the Ag-modified zeolite, which is indicative for the chemical nature of the rate-limiting step of the process. The data obtained are best fitted to the Freundlich adsorption isotherm. The Ag-modified clinoptilolite removes in 30 min over 80 % of Cr(VI), over 75 % of Cu(II) and over 70 % of Zn(II) that present simultaneously in an industrial wastewater. Due to its ability to remove Cr(VI) species, in combination with some heavy metal ions, some organic pollutants and exhibited antibacterial activity, silver loaded clinoptilolite seems to be a possible multifunctional reagent in the water and wastewater treatment and deserves further investigation.

1 Introduction

Hexavalent chromium, Cr(VI), appears in water due to natural and anthropogenic reasons. Oxidation of the chromium presenting in the igneous geologic formations is the natural source [1]. However, it is estimated that more than 70 % of Cr that is found in the environment comes from anthropogenic sources, such as nonferrous metals production (minerals beneficiation, metals smelting and refining), metals finishing and corrosion protection, paper and pulp mills, urban wastewater, etc. The effluents from these industries contain Cr(VI) at concentrations ranging from parts of the tenth to hundreds of mg/L [2]. It is established that both trivalent and hexavalent compounds of chromium are persistent in water [1]. Chromium (VI) is relatively mobile in water because its salts are more soluble than those of Cr(III) [3]. In natural waters Cr(VI) exists mainly as chromate (CrO_4^{2-}) or hydrogen chromate ($HCrO_4^{2-}$) ion [4].

The acute Cr intoxication via water ingestion in humans include severe gastrointestinal disorders, respiratory, liver and kidney injury, and cardiovascular collapse due to severe hypovolemia. The lethal dose is estimated at around 1 g of potassium dichromate ($K_2Cr_2O_7$) [5]. The exposure of human volunteers to Cr(VI) at a single dose of up to 4 mg and to Cr(III) or Cr(VI) at 5 mg in drinking water was not found to cause any adverse effect [2]. No apparent evident clinical changes or health effects were observed in humans who took Cr(VI) via drinking water at doses of between 0,03 and 4 mg per kg body weight (bw) per day for at least 3 days [2, 6]. However, gastrointestinal disorders including diarrhoea, abdominal pain, indigestion, and vomiting were associated with the chronic oral exposure of the general population in China to Cr(VI) through consumption of well water containing 20 mg Cr(VI)/L (considered to be equivalent to 0,57 mg Cr(VI)/kg bw per day). In addition, the oral exposure to Cr(VI) has been found to aggravate dermatitis of sensitive individuals [5].

Some *in vivo* studies showed that oral exposure to Cr(VI) was carcinogenic in rats and mice. The lowest-observed-adverse-effect levels in male and female rats and mice were 0,38 and 1,79 mg Cr(VI)/kg bw per day respectively [7]. Chromium (VI) shows broad genotoxicity that, together with its multispecies and multisite carcinogenicity, represents a strong evidence for a classification of Cr(VI) exposures through drinking water as probably to be carcinogenic to humans [3].

A guideline value of 50 μg/L drinking water is proposed by WHO and the EU for total Cr on the basis of the measurability by the available analytical methods, achievability by nowadays treatment technologies, and the data from toxicology studies [4, 8]. The proposal of the European Commission is this value to be reduced to 25 μg/L in 10 years after the new directive on the quality of water intended for human consumption will be enforced [9].

Different technologies have been applied and /or studied for removal of Cr (VI):

- Reduction coagulation filtration (RCF) - where Cr(VI) is reduced to Cr(III) by addition of ferrous salts or stannous chloride, followed by precipitation of $Cr(OH)_3$,

* Corresponding author: marichim@mgu.bg

the latter process very often aided by addition of ferric coagulants and the final step is filtration [10.]

- Ion exchange - column strong-base or weak-base anion exchange removed 95% of the Cr(VI) ions thus achieving levels below 5 μg/L [11].

- Membrane technologies, such as nanofiltration, reverse osmosis [12] and electrodialysis [13] have been successfully tested at laboratory level for Cr(VI) removal from model wastewater.

- Microbiological removal - activated sludge has been proved at laboratory level to be effective in reducing Cr(VI) to Cr(III) and precipitating the latter within biomass. However, the microbial methods may not be suitable for drinking-water and surface water treatment as chromium removal efficiency decreased with the increase of DO and Cr(VI) initial concentration and the best results were obtained under anaerobic conditions [14].

Each of the methods described above has its own advantages and disadvantages in dependence of the Cr(VI) concentration and the presence of other pollutants resulting in inadequate removal, the high initial and/or operational costs, toxic metals sludge generation and the need of its safe disposal.

Sorption is widely accepted as a suitable method for removing pollutants presenting in relatively low concentrations in the wastewater [15]. Conventional adsorbents such as activated carbon have been widely studied for their ability to remove chromium from water [16].

Recently efforts have been placed in nanomaterials by studying and searching for low-cost and environmentally friendly adsorbents. Activated carbon -based nanocomposites, carbon nanotubes and composites based on them, and graphene-based materials have been studied for their ability to remove Cr(VI) from wastewater by sorption. Metal oxides and metals-based nanomaterials as well as polymer-based nanomaterials have also been investigated for Cr(VI) sorption [17]. However, future studies are needed to investigate the cost-effectiveness and practical applicability of the nanomaterials usage.

Natural and non-expensive adsorbents are intensively searched for in order to reduce the treatment costs and the environmental load of the adsorption process and to ensure a sustainable environmental management.

Zeolites are abundant and relatively cheap aluminosilicate materials. They are non-toxic, thermally and chemically stable - features that render them good materials for pollutants removal by adsorption processes. Their building blocks are SiO_4 or AlO_4 tetrahedral structures, connected in different ways that leads to formation of different crystalline lattice structures and ensuring high specific surface area of these materials. The isomorphic framework substitution of silicon (+4) by aluminium (+3) causes appearance of a charge deficit that is accountable for the need of charge-balancing cations, in order to keep the neutrality of the zeolitic network. Alkaline (Na^+, K^+) or alkaline-earth metals (Mg^{2+}, Ca^{2+}) are the common charge-balancing cations. The mobility of these ions ensures the ion-exchange capability of zeolites for removing cationic species from different effluents [18].

However, due to the negative charge on their surface, zeolites possess very low to negligible affinity for the exchange of anions. In order to use their excellent physical properties, combined with their low price and environmentally friendless, researchers have conducted and are carrying out many studies to tailor zeolites in order to give them the ability to remove anions [19 - 21].

Generally, the following processes have been and are being applied: i) zeolites surface modification with surfactants that ensure availability of positive charge on the zeolite surface, ii) zeolites surface modification with metal ions that form insoluble compounds with the pollutants, and iii) zeolites grafting by using molecules with affinity for negative ions [20].

While the efforts on zeolites modification with surfactants started in the 90-ties of the previous century, the studies on modification with metal ions aiming at immobilization of anions have been developed in the recent 10-15 years [22 - 26].

Faghihian and Bowman [23], who were experienced also in the zeolite modification with surfactants, stated that the metal-modified zeolite showed higher Cr(VI) uptake compared to the surfactants-modified.

In addition, the application of metal-modified zeolites exhibits an advantage of easy preparation - by simple ion-exchange process. In some cases the zeolite could be initially used to immobilize other pollutant, such as lead ions and then already loaded material to be used for removing Cr(VI) [27].

Furthermore, it would be good if the sorbent is able to simultaneously immobilize some heavy metal cations together with Cr(VI) anions - a feature that is expected to be possessed by the metal-modified zeolite if its CEC is not entirely utilized. In the treatment of water, an additional advantage would be the possible bactericidal action of the material used. Zeolite loaded with silver ions (Ag^+), both further reduced or without reduction, showed antibacterial action against *Escherichia coli* and other microorganisms [28 - 31]. Last but not the least, silver loaded zeolite proved to be effective in the removal of an organic pollutant (xanthate) from model and clarified wastewater from flotation of zinc-lead ore [32].

The above described suggests that zeolite loaded with Ag^+ ions could be used as a multifunctional reagent in the treatment of waters contaminated with cations, anions and organic pollutants, e.g. wastewater from various industrial activities or of groundwater intended to be brought to domestic water quality. Since the number of studies using Ag^+-modified zeolites for removing anionic pollutants is relatively low [23, 33], in our opinion, a study on their ability to remove anions deserves the efforts.

2 Materials and methods

Natural zeolitic rock from Rhodopes region of Bulgaria was used. It was milled, the fraction 0.09-0.325 mm was separated by sieving and it was utilized in the experiments. The XRD analysis of the washed material has revealed that it contained 73% clinoptilolite. The classical silicate analysis was applied to determine the chemical composition of the material that was (in wt. %):

SiO_2 – 70,29, Al_2O_3 – 10,90, CaO – 2,97, MgO – 0,51, K_2O – 3,41, Na_2O – 0,46, Fe_2O_3 – 0,28, MnO – 0,04, TiO – 0,06, P_2O_3 < 0,05, SO_3 < 0,05, LOI – 10,99. The theoretical cation exchange capacity (TCEC) was found to be 215 meq/100 g zeolite. Silver ions (Ag^+) were loaded on the zeolite by placing it in contact with 0,1 M $AgNO_3$ solution at solid to liquid ratio = 1 : 20 for 6 hours, pH = 6 and magnetic stirring. Silver-loaded zeolite was washed with distilled water until negative reaction for Ag^+ in washings was reached. The amount of Ag^+ uploaded on zeolite (in this case 79 mg Ag/g zeolite) was calculated by using the data on the solution concentration before and after its contact with zeolite. More information on the zeolite modification and on the characterization of the metal-loaded zeolite can be found in our previous work [31, 32].

Stock solutions containing 1000 mg/L of Cr(VI) were prepared by dissolving K_2CrO_4 in distilled water. This solution was diluted with distilled water as required to obtain the solutions with different concentrations of Cr(VI) thus modelling polluted water. The solution pH was adjusted by adding 0,1 M HCl and 0,1 M NaOH solutions and measured by a laboratory pH meter. Concentrations of metal ions were determined by ICP-AES analysis after separating the solid and liquid phases by centrifugation (800 rev/min).

Experiments were conducted batch-wise: 0,5 g of zeolite, contacting with 50 mL of Cr(VI) bearing solution, was stirred with magnetic stirrer for corresponding time. Our preliminary studies showed as optimum the ratio 100 mL of wastewater to 1 g of zeolite (volume to mass – v: m) and the zeolite particles' size of 0,09-0,325 mm. Solutions containing Cr(VI) in the range from 5 to 30 mg/L (at pH 6) were deployed in the experiments aimed at studying the process kinetics, the impact of initial concentration of the pollutant and determining the adsorption isotherm. The impact of solutions pH value on the Cr(VI) immobilization was studied under the following conditions: concentration - 10 and 20 mg/L Cr(VI); contact time – 30 min and pH value of solutions to be treated 4, 6 and 8.

Table 1. Some parameters of the studied wastewaters

Water sample, Parameter	Sample 1	Sample 2	Sample 3
Ca^{2+}, mg/L	11,6	2,0	73,1
Mg^{2+}, mg/L	3,6	2,4	8,2
Na^+, mg/L	90,3	49,9	26,2
K^+, mg/L	0,7	1,9	3,3
HCO_3^-, mg/L	125,9	97,1	237,1
CO_3^{2-}, mg/L	6,0	18,0	-
SO_4^{2-}, mg/L	109,1	70,4	66
Cl^-, mg/L	12,4	7,8	7,2
Cr (VI), mg/L	16,8	23,2	33,8
Cu, mg/L	8,3	7,4	31,2
Zn, mg/L	19,3	8,8	61,2
pH	8,3	8,5	7,2
Cond., μS/cm	442	297	557

Desorption experiments were made in order to check how strongly Cr ions were immobilized by the silver modified zeolite. One g of preloaded zeolite (by its equilibration with solutions containing 20 mg/L Cr(VI)) was placed in contact for 8 h with 100 mL of distilled water and then the water was analyzed. The separated zeolite was dried and reused under the following conditions: 20 mg/L Cr(VI), pH 6, v: m = 100, 30 min.

In other series of experiments Ag^+-loaded zeolite was placed in contact for 30 min at v: m = 100 with samples of industrial wastewater that was partially treated in an enterprise - Table 1.

Data obtained were processed with the aid of EXCEL program.

3 Equations used

The pollutant removal from the initial solution, was calculated using the equation (1):

$$Removal,\ \% = [(C_o - C_t) / C_o] \times 100 \quad (1)$$

where C_o is the initial and C_t is the pollutant concentration (mg/L) at time t (min).

The quantity of immobilized pollutant q_t (mg/g) was calculated according to equation (2):

$$q_t = (C_o - C_t) \times V / m \quad (2)$$

where C_o and C_t - as mentioned above, m is the mass of the adsorbent (g) and V is the volume of the solution, contacting with the adsorbent (L). When equilibrium is reached the relation gives the amount q_e, (mg/g) of pollutant immobilized per unit mass of the adsorbent at equilibrium:

$$q_e = (C_o - C_e) \times V / m \quad (2')$$

and C_e is the pollutant concentration at equilibrium (mg/L).

Experimental data have been fitted to the equations describing the pseudo first order (PFO) - (3), the pseudo second order (PSO) - (4) and the Elovich - (5) kinetic models [34]:

$$\ln (q_e - q_t) = \ln q_e - k_1 \times t \quad (3)$$

$$t / q_t = 1 / (k_2 \times q_e^2) + t / q_e \quad (4)$$

$$q_t = (1/\beta) \times \ln (\alpha \times \beta) + (1/\beta) \times \ln t \quad (5)$$

where t, q_e and q_t are as described above, k_1 is the PFO rate constant [time^{-1}, 1/min] and k_2 is the PSO rate constant of adsorption [concentration^{-1} x time^{-1}, g/(mg x min)], α - the Elovich initial adsorption rate [concentration x time^{-1}, mg / (g x min)], β [concentration^{-1}, g/mg] - Elovich desorption constant.

Only data from the initial 20 min (that are not very close to the equilibrium) were considered, in order to avoid incorrect conclusions [35].

Isotherms equations that are most often tested in the literature for describing the adsorption from liquid phase, namely, Freundlich (6) and Langmuir (7) isotherms (used in their linear form) [17, 36], were checked for their ability to describe the adsorption equilibrium:

$$\log q_e = \log K_F + 1/n \times \log C_e \quad (6)$$

$$C_e / q_e = 1 / (K_L \times q_{max}) + C_e / q_{max} \quad (7)$$

where q_e, and C_e - as described above, K_F - Freundlich constant $[(mg/g)/(L/mg)^{1/n}]$, K_L is the Langmuir equilibrium constant (L/mg) - related to the free energy of adsorption and the reciprocal of the concentration at which half saturation of the adsorbent is reached, q_{max} (mg/g) is the maximum adsorption capacity, calculated by using equation (7).

Temkin isotherm (8) that takes into the account the adsorbent–adsorbate interactions and the Redlich–Peterson isotherm (9) featuring both Langmuir and Freundlich isotherms and describing sorption on heterogeneous surfaces were also checked (in their linear form) [17, 36] for their ability to describe the process:

$$q_e = B \ln A + B \ln C_e \quad (8)$$

$$\ln (C_e / q_e) = \beta \times \ln C_e - \ln k_R \quad (9)$$

where A [L/mg] - equilibrium binding constant that relates to the maximum binding energy, B = R x T / b is related to the heat of adsorption, R - gas constants ([J/(molxK)], T - temperature [K], b - the Temkin isotherm constant [J/mol], k_R - the Redlich-Peterson constant [L/mg] and β - dimensionless heterogeneity factor, q_e, and C_e - as described above.

4 Results and discussion

Results for Cr(VI) removal from model water as function of time at different initial pollutant concentrations are presented in Figure 1.

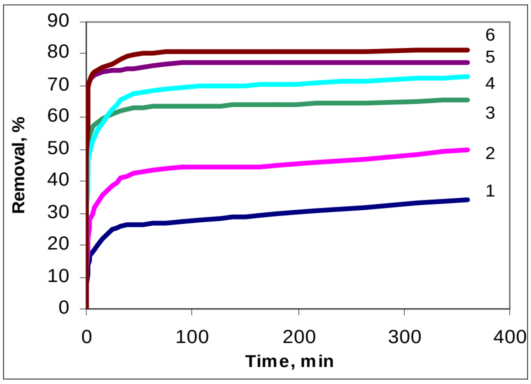

Fig. 1. Removal of Cr(VI) as function of time at different initial concentrations: 1 - 5 mg Cr(VI)/L, 2 - 10 mg Cr(VI)/L, 3 - 15 mg Cr(VI)/L, 4 - 20 mg Cr(VI)/L, 5 - 25 mg Cr(VI)/L, 6 - 30 mg Cr(VI)/L, pH 6, v : m = 100

As it can be seen from the Figure 1, the major part of the Cr(VI) removal occurred in the initial 25-30 min. That is why contact time of 30 min has been chosen in experiments aimed at studying the possible differences in Cr(VI) removal, due to influence of initial pH value of solution as well as the Cr(VI) removal from the real wastewater.

The immobilized amounts of Cr(VI) are of the same order of magnitude as the values described by other works for metal-exchanged (with best results for lead ions) forms of different aluminosilicate minerals, including natural clinoptilolite [25, 27]. However, use of Ag^+-loaded zeolite is more environmentally friendly, compared to Pb-loaded, and the additional advantage is the antibacterial activity of the material.

As it can be seen in the Figure 1, increasing the initial concentration of Cr(VI) increases both the removal (%) and the absolute removed amount of pollutant (mg/g). Similar influence of the initial pollutants concentration was found for the Cr (VI) removal by Martínez and co-authors [37].

The experimental data fitting to equations (3) - (5) showed that Cr(VI) ions immobilization is best described by the PSO kinetic equation, for which the coefficients of determination (R-squared) were the highest, followed by the Elovich model - Table 2. Similar order of kinetics models suitability is found for describing the adsorption of other noxious (arsenic) anions from aqueous solutions by use of manganese ferrite nanoparticles [34].

Table 2. The R^2 value for the studied kinetic models of Cr(VI) removal from model wastewater

Initial concentration, mg/L; Models	Pseudo-first order	Pseudo-second order	Elovich
5	0,993	0,994	0,982
10	0,945	0,999	0,996
15	0,960	0,999	0,997
20	0,986	0,999	0,994
25	0,989	0,999	0,998
30	0,992	0,999	0,995

Generally, kinetics description by the pseudo-second-order equation indicates that the rate-limiting step of immobilization process is of chemical nature. The removal process depends on the concentration of the dissolved pollutant in the solution and the available fraction of active sites of the adsorbent [38]. Most probably, the explanation lies in the formation of low soluble Ag_2CrO_4 on the adsorbents surface.

Another way to check the model adequacy is to compare experimental and calculated with the model values for the quantity of immobilized pollutant - Table 3 (data at 25th min). As it can be seen from Table 3, the PSO kinetic model quite satisfactory describes the process, the relative error for the calculated adsorbed amount is less that 10 % at all initial concentrations of Cr(VI).

The Elovich equation is generally applied to describe satisfactory kinetics of chemisorption for systems with heterogeneous adsorbing surfaces [34]. The relatively high values of R^2 obtained also for the Elovich equation implies the surface heterogeneity of the used modified clinoptilolite.

Table 3. Comparison of q_{exp} and q_{model}, calculated with PSO model.

Initial concentration, mg/L	q_{exp}, mg/g	q_{model}, mg/g
5	0,187	0,206
10	0,396	0,427
15	0,939	0,956
20	1,257	1,311
25	1,846	1,862
30	2,286	2,380

Experimental data fitting to the isotherm equations (6) - (9) showed that the process is well described by the Freundlich isotherm - Table 4.

Table 4. The R^2 value for the studied isotherm models of Cr(VI) removal from model wastewater.

Model	Freundlich	Langmuir	Temkin	Redlich–Peterson
R^2	0,995	0,897	0,937	0,985

In addition, the amounts $q_{e,}$ (mg/g) of pollutant immobilized per unit mass of the adsorbent at equilibrium, calculated using that model are near to the experimentally found (the relative error for the calculated adsorbed amount is less that 10 % for all studied initial concentrations) - Table 5. The process description by the Freundlich isotherm indicates that sorption occurs on heterogonous surfaces, and the obtained value n < 1 implies on the chemical nature of the bonding [17, 36].

Table 5. Comparison of q_{exp} and $q_{e,calc.,}$ calculated with Freundlich model.

Initial concentration, mg/L	$q_{e,exp}$, mg/g	$q_{e,calc.,}$, mg/g
5	0,256	0,2605
10	0,508	0,5329
15	1,0005	0,9106
20	1,461	1,3835
25	1,908	1,9929
30	2,415	2,5004

The immobilization process description by the PSO and Freundlich models has been reported also by other authors for Cr(VI) removal from waters by surfactant modified zeolite [19, 21].

Results showing the impact of wastewater initial pH value on Cr(VI) removal efficiency are presented in Table 6. As it can be seen from Table 6, the Cr(VI) removal is increased at higher pH value. Similar trend was observed for clinoptilolite modified with barium and zinc [27]. The findings could be attributed to the presence of different species of Cr(VI) at different pH values, and their affinity to silver and the stability of the formed surface species [17].

Results from desorption experiments showed that about 2 % of Cr(VI) were immobilised.

Table 6. Influence of wastewater initial pH on the Cr(VI) removal, in %, for 30 min

Initial Cr(VI) concentration / pH	4	6	8
10 mg/L	2,4	40,4	43,0
20 mg/L	3,6	65,6	82,4

When the zeolite was reused, the Cr(VI) removal in 30 min was 43,8 % implying for the possible use of the zeolite in more than one cycle.

Results from experiments with industrial wastewaters are presented in Table 7.

Considering the complicated water matrices (compared to the model waster - i.e. solutions prepared with distilled water), surprisingly good results for the Cr(VI) removal were found. Having in mind the parameters of the studied water samples (Table 1), as well as the observed influence of the initial pollutant concentration and the initial pH value (found for model waters - Figure 1 and Table 6), the good results could be ascribed to the impact of those factors.

Table 7. Pollutants removal from wastewater, in %, for 30 min

Water , pollutant	Sample 1	Sample 2	Sample 3
Cr (VI)	80,54	95,98	91,03
Cu(II)	95,1	86,6	76,7
Zn(II)	78,3	71,4	69,8

An additional positive result is the immobilization of copper and zinc ions, which is not unexpected and could be related to the unused entirely sorption capacity of the zeolite at its loading with silver ions.

5 Conclusions

Modification of natural Bulgarian zeolite - clinoptilolite by its loading with silver ions renders it able to immobilize Cr(VI) from practically neutral to slightly alkaline industrial wastewater.

Increasing the initial pollutant concentrations in the model wastewater (in the studied range) increases the removed amount (reaching 80 % in 45 min at initial concentration of Cr(VI) = 30 mg/ /L).

The kinetics of Cr(VI) immobilization by the Ag-modified zeolite is best described by the pseudo-second order kinetic equation that is indicative for the chemical nature of the rate-limiting step of the Cr(VI) immobilization.

The data obtained are best fitted to the Freundlich adsorption isotherm.

The silver-loaded clinoptilolite removes in 30 min over 80 % of Cr(VI), over 75 % of Cu(II) and over 70 % of Zn(II) that present simultaneously in industrial wastewater.

In conclusion, we can say that due to its ability to remove Cr(VI) species in combination with some heavy metal ions and some organic pollutants, as well as the exhibited antibacterial activity, silver loaded clinoptilolite deserves further investigation as a multifunctional reagent in the wastewaters treatment.

Abstract. The case study to determine the peculiarities of Miscanthus giganteus aboveground biomass formation depending on sewage sludge and composts rate carried out in the Precarpathian region of Ivano-Frankivsk province on sod-podzolic soils. The largest area of the leaf surface of miscanthus is formed in the trials where fresh sewage sludge was applied in the rate of 20 - 40 t/ha. The leaf surface area increases from 19 up to 24.0 cm2/plant, and the yield of raw mass of plants at the level of 23.5 - 25.1 t/ha due to increasing rates of sewage sludge application. The highest indicators of net photosynthesis productivity were found in the period of intensive growth, which amounted to 7.78 g/m²/day and in the maturation period of 7.56 g/m²/day in the trial SS - 40 t/ha + $N_{10}P_{14}K_{58}$. The amount of dry mass of miscanthus plants significantly depends on the height of the shoot and the leaf surface area of the plants. The use of compost based on sewage sludge and straw in a ratio of 3: 1 at a rate of 30 t/ha contributes to the dry weight of miscanthus plants at the level of 15 t/ha.

1 Introduction

The three main land-use groups in EU are: built-up areas, forest and agricultural land including mixed crop-livestock, pasture/livestock grazing, permanent crop production systems and bioenergy crops [1]. The biomass of energy crops occupies an important place in solving the problem of replacing traditional energy sources with alternative ones. Oil crops (82% of the land used for biodiesel fuel production) took first place in EU countries in 2015 [2]. The rest area for the production of ethanol crops (11%), biogas (7%), and heat generation (1%) used. Dedicated energy crops are mainly perennial grasses (miscanthus or switchgrass) and short rotation coppice such as willow or poplar. Poland, France, Germany, Spain, Romania, Sweden and the United Kingdom are the largest energy crops producer countries of the total European acreage [3-5]. For instance, withdrawn in 2009 short rotation plantations scheme was granted in Poland at national level for such energy crops as willow, poplar, Miscanthus and Sida hermaphrodita [6].

According to European experts, the area of land available for growing energy crops in 2020 will increase up to 20.5 million hectares, and in 2030 - up to 26.2 million hectares. Today 8 million hectares are unproductive in Ukraine [7]. Growing energy crops on marginal lands makes sense to estimate the use of some wastes. These wastes considered as fertilizers available to promote high yields [8]. Meantime the question about the fertilization impact on energy crops availability as biofuel is still an open debate [9, 10].

A wide range of feedstocks is available in abundance for biofuel production in industrialized countries using municipal solid waste [11]. The use of biomass residues, municipal and agri-waste as primary resource for biofuels is a promising proposal to reduce technogenic load connected with the waste disposal. Biomass is the biodegradable fraction of products, wastes, and residues of biological origin from agriculture (including plant and livestock), forestry, and related industries, including fisheries and aqua culture, as well as the biodegradable fraction of industrial and household waste [12]. Municipal sewage sludge considered as potential source of macroelements, which recovered during the production of energy crop biomass [13 - 16]. It is composed of a wide range of organic matter (OM), microorganisms, macro- and micro-nutrients, non- organic and organic micro pollutants [17] All these components indispensable for proper functioning of plants in optimum quantities and proportions for fertilization purposes [18]. However,

https://doi.org/10.1051/e3sconf/202128006009

sewage sludge also contains heavy metals, polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) [19-21]. The combination of different methods and the modification of chemical immobilizing agents both improved the fixation effect on heavy metals [22]. It allowed introducing municipal sewage sludge for growing crops at arable lands a dose of not more than 10 tons/ha for three years according to the Ukrainian state standard [23]. Large doses are possible in the case of mineland reclamation after three years monitoring, calculation of heavy metals uptake with energy crops yield and forthcoming life cycle assessment availability of municipal sewage sludge and other soil amendments application [24]. Fertilization at certain stages of the energy grass lifespan can maintain plantation production performance even in the later years of cultivation [25]. Agronomic and energy efficiency analysis to evaluate the effects of sewage sludge applied at rates equivalent to 100 and 160 kg N ha^{-1} on the production of giant miscanthus made [26]. Energy efficiency was 43–52% higher when giant miscanthus plants with sewage sludge rather than mineral fertilizers supplied. The highest energy value of biomass yield was in the treatments with 20MgDM$ha^{-1}$of sludge application [27]. The knowledge about the effect of large doses of sewage sludge on the energy crops longterm plantations is insufficient [28, 29]. Perennial herbaceous plants are considered to be promising for cultivation. Miscanthus as a relatively new energy crop for Ukraine requires additional study on the efficiency of cultivation in different soil and climatic conditions [30 - 32]. Miscanthus × giganteus can produce a high yield of aboveground biomass at relatively low input costs [33, 34]. Miscanthus can improve soil structure and levels of organic matter in marginal lands [35] and use for both liquid and solid biofuels production as raw material [36]. The crop characterize by extensive root/rhizome growth. This process can reduce soil compaction and allow a greater water buffering capacity [37]. The use of sewage sludge could not only increase yield but also positively affect biological and physico – chemical properties of soil profile [38]. It is known also that the intensity of organic matter accumulation depends on the size of the leaf surface, which is determined by the biometric parameters of plants and largely depends on their nutrition requirements [39, 40]. Miscanthus leaves take great importance for the formation and intensity of biomass accumulation [41]. During the season of plant vegetation, the shape and size of the leaf surface varies considerably [42, 43]. That is why it difficult to conduct biometric measurements. The aim of our research was to determine the dependence of the size of the leaf surface area and miscanthus biomass on different rates of sewage sludge and compost made on its basis.

2 Materials and methods

The field experiment was carried out during 2016 - 2019 in the sod-podzolic gley medium loamy soil at the territory of the Maidan village situated in Tysmenytsia district of Ivano-Frankivsk province. The scheme of field experiments included the following options: 1. Without fertilizers - control; 2. $N_{60}P_{60}K_{60}$; 3. $N_{90}P_{90}K_{90}$; 4. Sewage Sludge (SS) - 20 t/ha + $N_{50}P_{52}K_{74}$; 5. SS - 30 t/ha + $N_{30}P_{33}K_{66}$; 6. SS - 40 t/ha + $N_{10}P_{14}K_{58}$; 7. Compost 20 t/ha + $N_{50}P_{16}K_{67}$; 8. Compost 30 t/ha + $N_{30}K_{55}$.

The sewage sludge and straw mixed in ratio 3: 1 to prepare compost. Leaf area was determined by scanning 20 plants in each trial. After the measurement, the sheets were cut into pieces up to 25 cm long. The cutted parts of one sheet were folded into a transparent envelope (stationery file) in such a way that the individual pieces did not touch each other. After that, files with parts of the sheet were scanned. The same resolution was provided for all scanned images.

The analysis of the scanned images was performed using the Area S 2.1 program [44, 45]. The net productivity of photosynthesis was determined as the accumulation of dry matter per day per unit area of leaves. Measurements were performed during the growing season and determined the average. Net photosynthesis productivity defined as the accumulation of total plant biomass (every 20 days during the growing season) relative to the average leaf area over the same period.

Crop accounting performed by the method of continuous mowing of biomass in the accounting area and weighing the green mass to determine the dry matter content 3 times. The dry matter content determined by thermostatic weight method at a temperature of 105 ° C.

3 Results

During the four years of research, the average height of miscanthus plants in the field experiment varied from 1.85 m to 2.95 m (Table 1). The height of plants increased by 14 and 23% in the trials 2 and 3 respectively compared to the control. The additional height growth in three next options (4-6) was fixed in combination SS – 40 t/ha + N_{10} $P_{14}K_{58}$. During the application of compost based on sewage sludge and straw best result on height, number of plant stems and output of dry biomass was obtained in trial 8 (30 t / ha + $N_{30}K_{55}$). The number of plant stems increased with the amount of applied fertilizers based on sewage sludge at the rate of 20 - 40 t/ha (options 4 - 6) from 6 to 13 pieces/m^2 compared to the control (option 1). Application of sewage sludge and straw compost at the rate of 20 - 30 t/ha (options 7 - 8) led to the number of stems increasing up to 16 - 22 pcs/m^2 higher than at the control. The dependence of the leaf surface area on the height of miscanthus plants established using the method of correlation analysis (Fig. 1).The plant height and the leaf surface area were in the control variant 1.85m, and 11.5cm^2/plant correspondingly. The application of mineral fertilizers in the dose $N_{60\text{-}90}P_{60\text{-}90}K_{60\text{-}90}$ (options 2 and 3) increased the height of plants by 0.26 - 0.44 m, and the leaf surface area - by 2.0 - 2.5 cm^2/plant. The sewage sludge at the rate of 20 - 40 t/ha (options 4 - 6) impact on the plant height and leaf surface area was 2.24 - 2.72 m, and 18.5 - 23.8 cm^2/plant respectively.

Table 1. Miscanthus productivity parameters depending on sewage sludge rate application.

№	Trials	Height of the main shoot, m	Number of stems, pcs/m^2	Dry biomass yield, t/ha	Moisture content in biomass, %	The output of dry biomass, t/ha
1	Control	1.85	16	22.1	21.4	10.0

However, the leaf surface area of miscanthus plants was 6.1 - 8.4 cm^2/plant more than the leaf area of plants of the control variant in case of applying compost based on sewage sludge at the rate of 20 - 30 t / ha (options 7 and 8). The correlation dependence of the leaf surface area on the height of miscanthus plants described by the following multiple regression equation:

$$y = 7.1678 + 0{,}0143x,$$

where y – is the area of the leaf surface, cm^2/plant; x – plant height, m. It was determined that the leaf surface area of miscanthus plants depends on the height of the plant. This dependence can be considered as close, because the coefficient of determination is $R^2 = 0.69$, and the correlation coefficient r = 0.74.

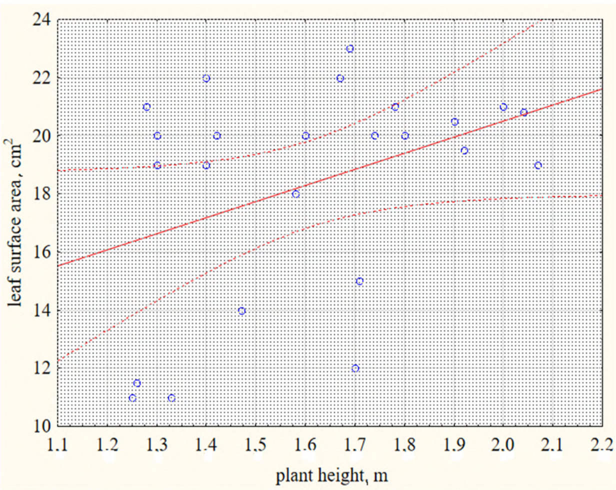

Fig. 1. Correlation dependence of leaf surface area on the height of miscanthus plants, average for 2016–2019.

The leaf surface area of miscanthus plants significantly depends on the number of stems and the height of shoots (Fig. 2).

The height of the dewlines was 2.24 - 2.72 m, the area of the leafy surface was apparently 18.5 - 24.0 cm^2/dewline, and the number of dewlines - 11.3 - 12.7 pcs/m^2 for the siege of sewage waters near the rate 20 - 40 t/ha (options 4 - 6).

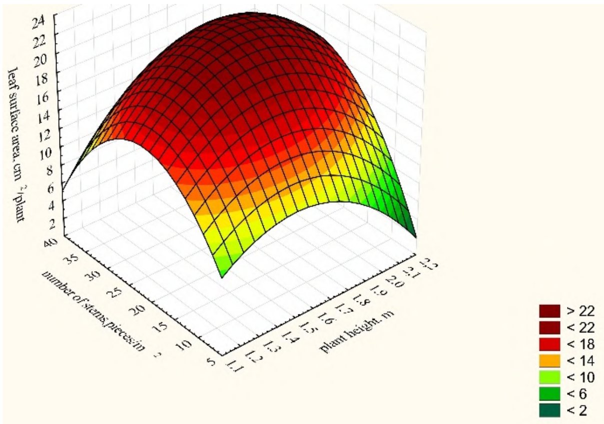

Fig. 2. Dependence of the leaf surface area on the number of stems and the height of the miscanthus shoot, average for 2016 - 2019.

The fallowness of the area of the leafy top of the number of stalks and the height of the pagoon of the muscanthus can be described by the following simple regression:

$$c = 1729.6509 - 14.683x - 75.8414y - 0.017x^2 + 1.2845xy - 2.5305y^2$$

where: c - the area of the leaf surface, cm^2/ plant; x - height of the growth, m ; y - the number of stems, pcs / m^2.

Miscanthus belongs to the plants of the C_4 group of photosynthesis, which are able to intensively accumulate the sun energy during the vegetation period [46]. This plant is highly resistant to diseases and pests [47]. About 95% of the total plant biomass is formed in the process of photosynthesis. The dynamics of accumulation of dry plant biomass reflects the intensity of its assimilation process [48]. The power of the assimilation apparatus and the duration of its operation is a decisive factor in the productivity of photosynthesis [49]. The dynamics of the formation of the photosynthetic apparatus in miscanthus is similar to other taller plants. [50]

The net productivity of photosynthesis (NPP) of miscanthus plants varies according to the surface area of the leaves (Table 2).

The introduction of 20 - 40 t/ha of SS and mineral fertilizers (options 4 - 6) impact on NPP at the initial growth was 3.64 - 3, 73 g/m^2 per day. The NPP at the initial growth increased and amounted to 3.65 - 3.69 g/m^2 per day with the application of composts based on sewage sludge (options 7 - 8). Meantime the NPP at the initial growth was 3.65 g/m^2 per day with the application of mineral fertilizers at the rate of $N_{90}P_{90}K_{90}$ (option 3).

Table 2. Net productivity of photosynthesis of miscanthus plants depending on fertilizer application rates, g/m^2 per day.

No	Trials	Initial growth	Intensive growth	Maturation
1	Control	3.55	7.45	7.30
2	$N_{60}P_{60}K_{60}$	3.61	7.58	7.39
3	$N_{90}P_{90}K_{90}$	3.65	7.63	7.45
4	SS 20 t/ha + N_{50} $P_{52}K_{74}$	3.64	7.61	7.40
5	SS 30 t/ha + $N_{30}P_{33}K_{66}$	3.68	7.69	7.47
6	SS 40 t/ha + N_{10} $P_{14}K_{58}$	3.73	7.78	7.56
7	Compost 20 t/ha + $_{0}P_{16}K_{67}$	3.65	7.60	7.38
8	Compost 30 t/ha + $N_{30}K_{55}$	3.69	7.65	7.44
	LSD $_{0.05}$	0.01	0.03	0.01

The NPP at the intensive growth of plants was the highest during the introduction of sewage sludge and was7.61 - 7.78 g/m^2 per day (options 4 - 6), which is 0.11 - 0.33 g/m^2 per day more than in control (option 1). The NPP at the intensive growth decreased by 0.1 - 0.4 g/m^2 per day with the application of composts (options 7 - 8) compared to the sewage sludge options 4 – 6 data.

The NPP during maturation remained the highest with the introduction of sewage sludge at the rate of 40 t/ha + $N_{10}P_{14}K_{58}$ and amounted to 7.56 g/m^2 per day. According to the obtained research results, the photosynthetic activity of plants in different vegetation periods remained the largest in the variants where sewage sludge was applied.

The net productivity of photosynthesis depended on the leaf surface area of miscanthus plants (Fig. 3).

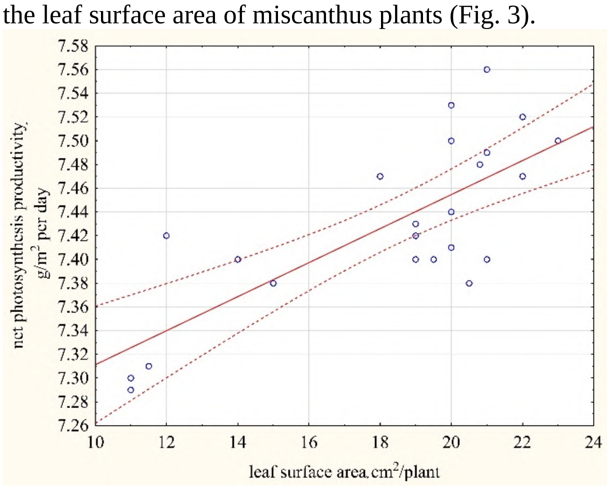

Fig. 3. Dependence of net productivity of photosynthesis on the leaf surface area of miscanthus plants, average for 2016 - 2019.

The net productivity of photosynthesis of miscanthus plants significantly depends on leaf surface area of miscanthus plants. The dependence of the net productivity of photosynthesis on the leaf surface area of the miscanthus plant described by the following regression equation:

$$y = 6.821 + 0.0556x$$

where: y is the area of the leaf surface, cm^2/plant; x – net productivity of photosynthesis, g/m^2 per day. The coefficient of determination R^2 was 0.79, i.e. the closeness of the connection can be considered as significant. There is a positive relationship between the net productivity of photosynthesis of miscanthus plants with the leaf surface area and the rate of fertilizer application. The dry mass yield of miscanthus plants depends on the height of the shoot and the area of the leaf surface of the plants (Fig. 4).

The dependence of the amount of dry mass of miscanthus plants on the height of the shoot and the area of the leaf surface can be described by the following equation:

$$c=12.1185-0.1587x+2.3991y-0.00766x^2+0.3554xy-0.71084y^2$$

where: c is the yield of dry mass of the plant, t/ha; x is the area of the leaf surface, cm^2/plant; y - plant height, cm. The multiple coefficient of determination (R^2 = 0.74) indicates a close correlation between these indicators.

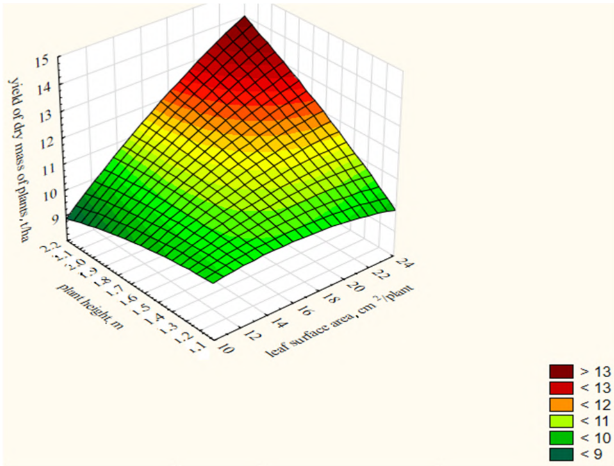

Fig. 4. Dependence of the accumulation of the dry weight of the miscanthus plant on the height of the shoot and the area of the leaf surface.

Thus, the highest productivity of miscanthus is achieved in the trials 7-8, where plants have the largest (24.0 cm^2/plant) leaf area. The coefficients of multiple regression are significant, since the actual value of the t-criterion exceeds the theoretical one by 5% of the significance level (Table 3).

According to the obtained results, the value of the regression coefficients for the yield of dry mass of plants (F_f = 196.32> $F_{0.05}$ = 1.22) is -26,356 with a standard error of 62.9 and the materiality criteria tf (t $_{0.05}$ = 1.33) is equal to 7.2. Thus, the value of the regression coefficients for the leaf surface area (F_f = 66.254> $F_{0.05}$ = 1.22) is -87.4178 with a standard error of 25.1 and a materiality criterion ($t_{0.05}$ = 1.33), which equal to 3.5.

Table 3. Coefficients of multiple regression of the dry weight and the leaf surface area of the miscanthus plant.

The yield of dry mass of the plant (F_f=196.32> $F_{0,05}$=1.22)			
Regression coefficients	**Values of regression coefficients**	**Standard error Sb**	**Significance criteria t_f ($t_{0.05}$ =1.3)**

4 Discussion

The dependence of the dry mass of the plant on the shoot height and the leaf surface area based on several biometric parameters. The genetic and physiological mechanisms underlying biomass production of the *Miscanthus* species awaits further investigation [51]. It was described also highly significant dependence of the number of stomata on the leaf surface and age [52]. The morphometric analysis confirmed higher growth performance of the fertilized trials [53]. Our case study results are consistent with other conclusions that the yield, specific leaf area and leaf area index of Miscanthus stimulated by N fertilization [54]. The greatest impact on the leaf surface of miscanthus in our field experiment has the height of the plant, the number of stems, which, in turn, depending on the application of fertilizers.

The yield of dry mass of plants depends on the area of the leaf surface and the height of the plant. Miscanthus requires intense sunlight during the growing season to form the optimum leaf area and accumulate sufficient organic matter [55].

The net photosynthetic productivity of miscanthus plants in our research was closely related to the leaf surface area. This dependence characterized by high density (R^2 = 0.79).

5 Conclusions

It was found that the greatest impact on the leaf surface of miscanthus has the height of the plant and the number of stems, which, in turn, depend on the application of fertilizers. The yield of dry mass of plants depends on the area of the leaf surface and the height of the plant. The largest area of the leaf surface of miscanthus is formed in the trials where fresh sewage sludge was applied in the rate of 20 - 40 t/ha. The leaf surface area increases from 19.0 up to 24.0 cm^2/plant with increasing rates of SS application. The highest indicators of net photosynthesis productivity were found in the period of intensive growth, which amounted to 7.78 g/m²/day and in the maturation period of 7.56 g/m²/day in the trial 6 (SS - 40 t/ha + $N_{10}P_{14}K_{58}$). The amount of dry mass of miscanthus plants significantly depends on the height of the shoot and the leaf surface area of the plants. Multiple coefficient of determination (R^2 = 0.74) indicates a close correlation between these indicators. The use of compost based on sewage sludge and straw in a ratio of 3:1 at the rate of 30 t/ha contributes to the dry weight of miscanthus plants at 15 t/ha.

The studies were performed on sod-podzolic soils, which are characterized by relatively low organic matter content, low antidegradation resistance, unsatisfactory agrophysical and agrochemical properties. Thus, the conducted research can serve as a model experiment and be extrapolated to such soils, which are marked by manifestations of degradation of various degrees. In addition, the problem of environmentally safe disposal of sewage sludge is gaining global scale and needs to be addressed. The performed researches partially give the answer to the decision of this problem. One of the ways to solve it is to use sewage sludge as fertilizer for energy crops. Therefore, the studies can be of practical value for use in different regions on other types of soils, which are characterized by varying degrees of degradation processes, which will increase the ecological sustainability of agroecosystems.

Forecasting of the number of bird collisions with turbines in the territory of Pre-Azov region wind park using the route census method

Volodymyr Yeremieiev[1,*]

[1]Bogdan Khmelnitsky Melitopol State Pedagogical University, 20 Hetmanska Str., Melitopol, 72300, Ukraine

Abstract. The information system has been designed to ensure the analysis of information on the monitoring results of the wind power plant (WPP) territory using the route census method. The database contains 48 fields, reflecting the monitoring results of birds' behavior in the territory of WPP and processing the initial data: year, month and day of observation, a number of birds of this species, flight altitude, flight speed, direction of flight, coordinates of the bird registration point on the Google-map, average number of birds flying over the territory of the wind park at a given time, coordinates of the points of intersection of the bird flight path with the perimeter of the wind park or observation site, the length of bird flight path over the observation site, and other parameters. The analysis of distribution of birds in the territory of the "Primorsk-1" WPP according to the types of migration (forage, transit, nesting, and ground), direction of flight and altitude characteristics has been carried out. The total number of registered birds was 8927 specimens of 72 species, of which 802 specimens of 11 species were referred to the transit type, 2511 specimens of 32 species – to the forage type, 5614 specimens of 60 species were on the ground (ground type). Most birds (63%) belong to the ground type. 28% of birds were registered in the forage group, 9.0% of birds were flying in transit. The greatest activity of birds is manifested in the autumn migration season, when the transit group accounts for 77% of all annual transit flights. The proportion of birds of forage and ground types, registered in autumn, is 68% and 74%, respectively, of the total number of birds registered in autumn. In the group of ground birds, the overwhelming majority of specimens belong to the period of autumn migration (4141 birds or 74%). The least number was observed in the winter season (317 birds or 5.6%). The author proposes a mathematical model for analyzing birds' interaction with turbines using the results of monitoring the territory of wind power plants by means of route census method. The model makes it possible to obtain information on the probability of different species of bird collisions with wind wheels and the number of collisions with turbines, depending on the flight characteristics of birds, parameters of wind parks and observation conditions in different seasons. In the risk zone of birds' interaction with turbines, only specimens of one species, Buteo buteo, were observed. The calculated probability of one bird collision when passing through the wind wheel is 0.19. The anticipated number of bird collisions with turbines during one year of the "Primorsk-1" wind park functioning is in the range of 5.6÷6.7 specimens.

1 Introduction

The intensive development of wind energy has a certain impact on the environmental situation, especially noticeable in cases where wind power plants are located in places where bird communities are concentrated. The negative impact of wind turbines on ornithofauna is of global concern [9] [13] [24] [26]. According to the data [17], eleven wind power plants at the Spanish station in Navarro 20.6 vultures and several thousand of small birds are killed by one turbine annually. Only in two regions of Spain in the period from 1993 to 2016 the number of dead birds of 170 species and bats were 10,017 specimens [23]. Winkelman [27] reports that mortality rates of large birds on the coast are estimated at 2.4-56.2, and for passerines at 2.1-63.8 specimens/ turbine/year. In the territory of the wind power plant in the United States, 140.000-328.000 birds [18] and 0.5÷1.6 million bats [8] die annually.

The territory of most of the used and projected wind power plants in Ukraine is located on the Azov and Black sea coasts. In 2020, the energy company DTEK completed the construction of the second stage of the Primorsky wind park in the Zaporozhye region next to the operating 200 MW Botievo WPP. Earlier, in May, the first stage of the station, which is located near the city of Primorsk, was launched (Primorsk Wind Park, 2020). Migratory bird complexes of the Azov-Black Sea ecological corridor are characterized by a great diversity in species composition, large-scale in numbers in Eastern Europe and they are significant in the number of rare and endangered species, which are protected by the Bonn Convention and the Agreement on the Conservation of

* Corresponding author: eremeev_v@mdpu.org.ua

Migratory Birds on the Afro-Eurasian Transcontinental Routes [6]. Therefore, the study of transcontinental migration flows is extremely important for assessing possible negative impact of wind power plants on the behavior of birds in the territory of wind power plants and adjacent zones.

The foundations of the analysis and, in particular, the anticipation of the state of the birds' biodiversity in the studied territories are the results of long-term monitoring. The methodology for the anticipation of the number of bird collisions with wind turbines is described in the recommendations of the Scottish Natural Heritage Foundation (Scottish Natural Heritage, 2014). The reliability of these recommendations has been confirmed by many researchers [16] [20] [15] [21]. The recommendations of the Scottish Natural Heritage Foundation provide for monitoring at several stationary sites belonging to the wind power plants. The size of the selected sites, as a rule, does not exceed 10÷20% of the total area of the wind park.

The deployment of wind power facilities in one of the most powerful migration routes in Eastern Europe predetermines the need to study the state of biodiversity in the territories of the wind power plants. Project work to substantiate the impact of WPP on the ornithological bird complexes within Primorsk district of Zaporozhye region was carried out in 2011-2017 [1] [6] using the recommendations of the Scottish Natural Heritage fund. Based on the data obtained, the analysis of the possibility of bird death due to their collision with the rotor blades at the "Primorsk-1" wind power plant was carried out [4].

An alternative way to obtain information is the route census method, adapted by Siokhin V.D. and Gorlov P.I. in relation to collecting data necessary to anticipate the impact of wind power plants on the environmental situation [3] [7]. The route census method allows collecting information on the behavior of birds from almost the entire territory of the wind power plant, therefore, in this scientific work, this method is used as a main one. The obtained statistical data processing is not possible without the involvement of modern computer technology. In the scientific works [1] [4] [6] [21] [25] information systems and ornithological databases have been created to ensure the storage and analysis of the results of bird calculations in the Pre-Azov region in 2015-2020. The given research work is devoted to the development of these studies in relation to the monitoring of bird complexes in the territory of "Primorsk-1" wind park using the route census method.

2 Aim and methodology of research work

1. Research work aim. The aim of the research work is to anticipate the interaction of birds with the turbines of the "Primorsk-1" WPP, based on the analysis of the results of monitoring the territory of the "Primorsk-1" wind park, which was carried out in 2018 using the route census method. To achieve the aim, the following objectives were formulated:

• development of information system to ensure the analysis of information, based on the results of monitoring the WPP territory using the route census method

• identification of birds distribution according to the direction of migration and altitudes in the territory of the "Primorsk-1" station,

• design of a mathematical model for anticipating birds' interaction with turbines, based on the results of monitoring the wind park's territory using the route census method,

• anticipation of the number of bird collisions with turbines in the territory of the "Primorsk-1" wind park.

2. Methodology for monitoring the territory of WPP. The monitoring time was chosen so as to cover all periods of bird's life: winter period 2018.01.25, 2018.02.16, spring migration season 2018.03.10, 2018.03.20, 2018.04.11, nesting period 2018.05.05, 2018.05.23, autumn migration season 2018.09.15, 2018.09.29, 2018.10.13. The observations were made in the morning and evening hours lasting approximately 3 hours each with a total observation time of 63 hours. The scheme of one of the route census, related to the observations of 2018.03.20 and linked to the Google map for the northeastern part of the territory of the "Primorsk-1" wind park, is shown in Fig. 1.

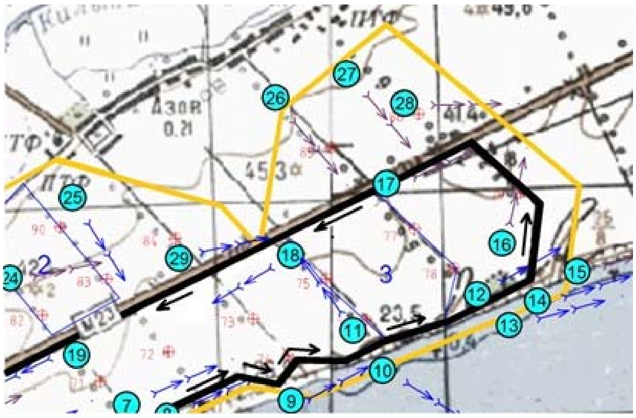

Fig. 1. Scheme of route census 2018.03.20 in the territory of the wind park "Primorsk-1".

The territory of the wind park is an irregular polygon with sixteen vertices; in Fig. 1 its boundary is painted in yellow color. The observer was moving by car at a speed of less than 10 km/h. The vehicle's trajectory is represented on the map by the segments, painted in black color, the direction of movement is indicated by black arrows. At first, the movement was carried out along the sea coast in a northeast direction. As the observer was moving, he registered several groups of birds in positions with numbers 9÷15, which are circled in Fig. 1.

For each group of registered specimens, the flight altitude, number of birds of a certain species and direction of migration, which is indicated by arrows on the map, were registered. For example, at the position, marked with the no.9, at 10:00 am, 6 specimens of Podiceps cristatus of the forage type, flying in a northeastern direction at an altitude of 10m, were registered. This mode is typical for birds that constantly inhabit the wind park's territory or the buffer zones. Approximately 500m from the eastern border of the wind power plant, the direction of the route has changed first to the north, then to the north-west. Here at 11.00 a.m. in position no.16 at an altitude of 10m, a flock of 14 specimens of Motacilla alba was found. This group of birds was flying in a northeastern direction. Then the route continued in a southeastern direction, where various specimens were observed at positions no.17-19. After reaching the southeastern part of the wind park territory, the route turned north, passed along its northern part, turned south and returned to its western boundaries.

Route census method covered about 75% of the wind power plant’s territory, which is several times larger than the area of sites that are usually involved in the method ("Scottish Natural Heritage", 2014). The monitoring results, obtained by the route census method, contained the following data on the behavior of birds in the WPP territory: season, month, day and hour of registration; place of registration, linked to a Google map; number of birds; bird species; flight direction; type of stay in the territory of WPP (transit, forage, ground); flight altitude. An example of the monitoring results, using the route census method, is presented in table. 1.

Table 1. Monitoring results of number of n-birds of forage type in the territory of "Prymorsk-1" wind park 2018.01.25 NE – north-east, S – south, SW – south-west.

No	Time	Sprcies	N	Type of migration	Altitude (m)	Direction
1	11.00	Sturnus vulgaris	25	forage	7	NE
2		Buteo lagopus	1	forage	30	S
3		Larus cachinnans	18	forage	15	NE
4	12.00	Larus cachinnans	21	forage	10	NE
5		Fringilla coelebs	20	forage	5	SW
6	14.00	Larus cachinnans	7,3,2,2	forage	10	SW
7		Larus cachinnans	1,1,5,3,4,4	forage	10	SW
8	16.00	Buteo lagopus	1	forage	30	SW
Total		5 species	118			

Similar tables contained the results of the registration of migratory flows of birds, which were carried out in 2018.

3. Methodology for processing observation results. The processing of monitoring results should provide information on the behavior of birds in the territory of WPP according to the basic characteristics, which are necessary to anticipate the impact of wind power plants on ornithocomplexes [3] [6] [21] [25], namely:

• a number of birds of the observed species in the territory of the wind park in different seasons of the year,
• distribution of birds by altitude,
• time, spent by birds in the risk zone (RZ) of collision with wind turbines,
• probability of bird collision with the turbine blades when it is in RZ,
• anticipated number of bird-turbine collisions.

The probability of a collision of a bird of the j species with turbine blades when it is flying through the danger zone of a wind park is [11] [12]:

$$P_j = p_j(r,\phi) r dr d\phi / \pi R^2 , \qquad (1)$$

where

$p_j(r,\varphi)$ - probable density of a bird collision,
r - distance from a bird to the turbine center,
φ - angle of turbine blade rotation,
R - radius of the turbine wind wheel.

The danger zone (ZD) is a part of the area of the entire wind power plant, where the rotating turbines are located. The cubage of the danger zone is

$$V_{Zd} = M\pi R^2 d \cos(\gamma), \qquad (2)$$

where

M – a number of turbines in the station territory,
d - average value of the width of the wind wheel blade,
γ - blade wedge angle between its chord and the plane of rotation of the wind wheel.

Let n_{jZd} birds of j-species are flying through ZD. Then the number of their collisions with the turbine blades is identified by the formula

$$n_j = f n_{jZd} P_j, \qquad (3)$$

where

f - coefficient of evasion, which determines the ability of the bird to change the direction of flight near the wind wheel and, thus, to avoid collision with it; the most probable value of the coefficient f is in the range 0.05÷0.005 (May, Hoel, & et al, 2010; Furness, 2015),

P_j, - probability of collision of birds of j-species, flying through the turbine, is identified by formula (1).

Let us introduce the concept of risk zone (RZ) of interaction of birds with rotors. Under RZ we mean a part of the space in the interval of altitudes $\delta H = H_2 - H_1$ between the lower $H1$ and upper $H2$ levels of the turbine wind wheel on the observation site with the area S_{Rz}. The cubage of the risk zone V_{Rz} is

$$V_{Rz} = \delta H S_{Rz}. \qquad (4)$$

Let during the monitoring of T_{Rz} i-groups of birds of j-species were taken into account in the number of n_{ij}, each of which was in RZ during t_{ij}. The total number of birds of j-species n_{jDz}, flying through RZ during the operation of the station is (Band, W., 2000; Osadchyi V. et al. 2019)

$$n_{jDz} = \frac{V_{Dz}T_{Lc}}{T_{Rz}V_{Rz}}\sum_i n_{ij}l_{ij}, \quad (5)$$

where

$l_{ij}=t_{ij}v_j$ - length of the bird's trajectory at the observation site,

t_{ij} - time of bird's flight over the observation site with a speed vj,

T_{Lc} - duration of bird's life cycle during the wind park functioning for some time.

Substituting the values of V_{Dz} and V_{Rz} from formulas (2), (4) into (5), we obtain

$$n_{jDz} = \frac{M\pi R^2 \cos(\gamma) d T_{Lc}}{T_{Rz}\delta H S_{Rz}}\sum_i n_{ij}l_{ij}. \quad (6)$$

According to formulas (3) and (6), the number of collisions of birds of *j*-species with turbine blades is identified by the formula

$$n_j = \frac{M\pi R^2 \cos(\gamma) d T_{Lc} f P_j}{T_{Rz}\delta H S_{Rz}}\sum_i n_{ij}l_{ij}. \quad (7)$$

The value of the integral (1) is estimated by the formula [21]:

$$P_j=[\pi R_0^2+6(R-R_0)L_{2j}/\pi+3(R-R_0)d+3(R-R_0)^2\omega t/2]/(\pi R^2), \quad (8)$$

where

L_{2j} - wingspan of the bird,

ω - angular speed of turbine rotation,

R_0 - radius of the rotor sleeve where the blade is attached,

T - time of flight of *j*-species bird through the rotor with speed v.

The time of flight t is identified by the formula

$$t= (d\sin(\gamma)+L_{1j}))/v, \quad (9)$$

where

L_{1j} - length of the bird.

The distance from the ground to the bottom of the rotor is $H1$=48m, to the top – $H2$=182m. The blade length is 67 m, the width at the widest point is 4.1m, maximum rotation speed of the wind wheel is 14 rpm. The shape of the observation site can be represented as a circle with an area of about 1 km^2, in the center of which the observer is located.

3 Results of work

1. *Description of the developed information system Birds2*. The designed program ensures the storage and processing of data, obtained during monitoring the wind park's territory using the route census method. The program code is based on *Windows Forms* technology in the *Microsoft Visual Studio Community 2019* software development environment. Initiating the program execution displays the main window. In its upper part there are three tabs "Database", "Calculation", "Request", which provide switching the execution of commands between program blocks. When you start the program, the "Database" tab is displayed by default. It contains the *dataGridView* element with the original data.

Information is loaded into the spreadsheet automatically from the database file of *Microsoft Access "birds2.mdb"*, which is located in the folder with the executable file *"Birds2.exe"*. The spreadsheet contains information on the results of monitoring the behavior of birds in the territory of the wind power plant and processing the obtained data. It consists of 48 fields:

1. Code – serial number of the record in the database.
2. Date – year, month and day of observation.
3. No. – number, corresponding to the entry on the Google map.
4. Time – time of observation.
5. *t* – duration of observation in hours for the selected observation day.
6. Species – birds belonging to definite species.
7. Number – number of birds.
8. Type of migration – the way of birds' movement and their presence on the observation site (transit, forage, nesting).
9. Altitude (m) – flight altitude in m.
10. Speed (km/hour) – bird's flight speed in km/h.
11. Direction – flight direction (N - north, NE - northeast, NW - north-west, W - west, SW - southwest, E - east, SE - south-east, S - south).
12. *tg* - tangent of the angle between the direction of flight and the abscissa axis.
13. *t* u (km) - coordinates of the bird registration point on the Google-map on the abscissa axis in km.
14. *v* (km) - coordinates of the bird registration point on the Google-map along the ordinate in km.
15. *x1÷x16* - sixteen coordinates on the abscissa axis in km for the points of intersection of the bird's flight path with all lines that pass through the sides of the polygon that are the boundaries of the wind power plant.
16. *y1÷y16* - sixteen coordinates on the ordinate axis in km for the points of intersection of the bird's flight path with all lines that pass through the sides of the polygon that are the boundaries of the wind power plant.
17. Number - the number of sides of the polygon, which are intersected by birds' flight paths at the entrance and exit of the wind power plant.
18. Length of flight - the average number of birds, flying over the territory of the wind park at a given time.

When the program starts, the display shows the original information, contained in the data file. In the lower left corner of the spreadsheet, information is displayed about the number of records contained in the spreadsheet in the "Database" tab. The spreadsheet is viewed by scrolling the mouse wheel or moving the slider in the horizontal and vertical directions in the lower and right parts of the window using the arrow keys "left", "right", "up", "down".

The coordinates of the points of intersection of the bird's flight path with the boundary of the wind park territory are determined automatically using a specially created calculation block. The color of the active (highlighted) line determines the type of migration: blue indicates the type "forage" or "transit", green indicates the type "ground".

In the lower right part of the main window there is a button "Calculation". Pressing this button you start the process of calculating the number of birds of the transit type of flight (*Ktr*), forage type of flight (*Kforage*), ground type (*Kground*) and the total number of birds (*Ksum*). The *K* index denotes a calculated parameter that characterizes the average value of the number of birds present in the wind park at a given time. The value of K could be obtained based on the results of photographing the territory of the wind park from a flying vehicle. If *M* birds are found in m photographs of this kind, then the value of the parameter *K* is equal to the ratio *M/m*. To calculate the value of *K*, a special program block is drawn up.

The calculation results are displayed on the screen in the form of a message window.

Next to the "Calculation" button is the "Map" button. It opens a new window designed for viewing a Google map, indicating the boundaries of the wind power plant in yellow color, the route of observation and places of observation of birds. To display the map on the screen, you must press the "Select file" button in the upper right corner of the window. A dialog box will appear on the screen, in which you should specify the path and select the file with the "jpg" extension for viewing. A map will appear in the center of the screen. Under the button "Select file" there is an element "label", which reflects the coordinates (km) of the mouse cursor on the map.

Clicking the left mouse button at a certain point on the map is resulted in the appearance of a red cross under the cursor. The coordinates of the marked point will be displayed above the "Add coordinates" button. This button copies the coordinates to the *"u(km)"* and *"v(km)"* fields of the spreadsheet located in the "Database" tab of the main window. The selected coordinates are copied to the active (selected) table row. Information in the active line is displayed in the lower part of the "Map" window (entry code, entry date and number that corresponds to the designation of the entry on the map). The "Map" window is also used for the initial filling in the *"u(km)"* and *"v(km)"* fields.

In the second tab of the main window "Calculate" there is a spreadsheet that reflects the data, calculated on the basis of the entries of the first spreadsheet in the "Database" tab for a specific direction and altitude of birds' flight. Namely:

- a number of bird species;
- a total number of birds;
- a number of birds of forage type, transit type and nesting type;
- an average number of birds in the territory of the wind park at a given time.

At the bottom of the tab the information about dates of various types is displayed:

- a date or dates that were requested in the "Request" tab;
- a date or dates that meet the conditions of the request;
- a date or dates that meet the conditions of this request and are referred to the entries with the "forage" and "transit" flight types.

Calculations are carried out on the basis of a request for the entries using the third tab "Request", where the forms that ensure the fulfillment of the conditions for selecting data from the spreadsheet from the tab "Database" are displayed. The choice is made according to four parameters:

- species of birds;
- flight date;
- direction of flights;
- type of flights.

Sample request provides a selection of all registered birds of a transit type in the territory of the wind park that were flying in 2018.09.15 in a western direction. The choice of initial data is carried out using the forms in the headings "All values" or "Selectively". "Selectively" mode defines a list of selected parameters from the existing options. Installation of one or several arbitrary options is allowed.

After setting the request, you have to leave the "Request" tab and go to the "Database" or "Calculate" tab. The program automatically performs all actions in accordance with the request. Information from the database that meets the set request is displayed in the "Database" tab, and a number of birds is displayed in the lower right corner of this tab. After the user leaves the "Request" tab, the data from the "Calculation" tab are automatically recalculated in accordance with the new information from the "Database" tab.

2. *Distribution of birds by types of migration and altitudes*. The total number of registered birds was 8927 specimens of 72 species, of which 802 specimens of 11 species were of the transit type, 2511 specimens of 32 were of the forage type, 5614 specimens of 60 species were of the ground (terrestrial type). 4 birds *Buteo buteo* were registered in the risk zone of the collision with turbines (RZ). The quantitative characteristics of birds of various types according to the season are given in table 2.

Table 2. Distribution of birds by type of migration.

Type of migration	Winter season	Spring migration	Nesting season	Autumn migration	Total
Transit	0	128	53	621	802(9,0%)
Forage	277	375	162	1697	2511(28%)
Ground	317	592	564	4141	5614(63%)

As it can be seen from table 2, a majority of birds (63%) belongs to the ground type. In the forage group 28% of birds were registered, the remaining 9.0% of birds were flying in transit. The greatest activity of birds is manifested in the autumn migration season, when the transit group accounts for 77% of all annual transit flights. The proportion of birds of forage and ground types, registered in autumn, is 68% and 74%, respectively, of the total number of birds registered in autumn. Data on the number of species and number of birds of the ground type in different seasons are given in table 3.

Table 3. Distribution of birds by type of migration.

Season	Winter season	Spring migration	Nesting season	Autumn migration
Number of species	13	25	35	43
N	317	592	564	4141

Of the total number of ground type birds, the largest part of them belongs to the period of autumn migration (4141 or 74%). The least number was registered in the winter season (317 birds or 5.6%).

Analysis of migratory flows showed that only 277 specimens of six species of the forage group were flying by in winter. At an altitude of up to 10 m, 66% of birds were registered, in the range of altitude (11÷25) m – 32%, in the range of altitude (26÷50) m – 2%. There were no birds in the risk zone.

The spring migration period was distinguished by a higher diversity of species. The forage group included 375 birds of 22 species, the transit group – 128 birds of 6 species. In RZ, at an altitude of 100m, two forage-type *Buteo buteo* birds were found. In the range of altitude (26÷50) m, one bird was registered, in the range of altitude (11÷25) m – 40 birds (8%), the remaining 460 specimens (91%) were flying at an altitude of up to 10m.

During the nesting period, 162 birds of 10 species of the forage group and 53 birds of one species *L.melanocephalos* of the transit group were counted in flight. No birds were found in RZ. At an altitude of up to 10m, 134 (62%) birds were flying by, in the range of altitude (11÷25) m – 40 (8%), in the range of altitude (26÷50) m – 70 specimens (32.5%).

The total number of migratory birds in the autumn period was 2318, belonging to 26 species. Out of these, 1697 specimens of 21 species belonged to the forage group, 621 specimens of 8 species – to the transit group. 1591 (68.6%) birds were flying at an altitude of up to 10m, in the range of altitude (11÷25) m – 173 (7.5%), in the range of altitude (26÷50) m – 350 (15.1%) birds. In RZ, at an altitude of 150m, 2 (0.1%) *Buteo buteo* birds of the forage type were found, 202 (8.7%) specimens were flying above 150 m.

Thus, out of 72 species in RZ, only one species, *Buteo buteo*, was registered in the amount of 4 birds. During the monitoring period, 16 representatives of this species were registered, most of which were outside the RZ.

Designed program differs from other information systems, described in the scientific works [1] [21] by the ability to identify a number of characteristics of birds of the transit type, which are necessary for the anticipation of their collision with turbine blades:

• coordinates of points of bird's flight path intersection with the perimeter of the wind park or observation site,

• length of the bird's flight path over the territory of the wind park,

• average number of birds flying over the territory of the wind park at a given time.

3. *Anticipation of the interaction of birds of the species Buteo buteo with turbines*. The results of monitoring the territory by the route census method provide information only about the altitude and direction of flight. Bird migration trajectories are characterized by a great diversity. An example of flight trajectories of specimen, registered in the territory of the "Primorsk-1" wind park, during the autumn migration is shown in Fig. 2.

Fig. 2. Sample flight trajectories of specimens, registered in the territory of the "Primorsk-1" wind park during the autumn migration.

At low altitudes, birds usually fly along curved trajectories such as (4), (5) in Fig. 2. The vast majority of birds, registered in RZ and above it, were flying along straight lines (1), (2), (3), (6), (7). In order to estimate the length of rectilinear trajectories l_{ij} in formula (7), we represent the shape of the observation site as a circle of radius r with area $SRz = \pi r2$, in the center of which the observer is located. The SRz value is about 1 $km2$. In this case, the viewing radius r is 560 m. The length of the bird's flight path in the observation site was 880 m. The flight speed was taken to be vj=11,6 m/sec.

The tij value in this case is 75.9 sec.

To anticipate the interaction of birds with turbines according to formula (7), we need information on the duration of the bird's life cycle during the year of the wind park functioning. Two cases may arise here:

• a number of bird collisions with turbines is identified in each season separately, taking into account the results of monitoring by seasons,

• a number of bird collisions with turbines is identified during a year, taking into account the total monitoring results for one year.

In both cases, the same formula (7) is used, but due to different values of the parameters TLc (duration of the bird's life cycle) and $TRisc$ (duration of monitoring time), the results will not be the same. With a sufficiently large statistical sample of birds in the RZ, the first case should be preferred. The corresponding data on the value of TLc in different seasons with duration of TRz in relation to one year of wind park "Primorsk-1" functioning are presented in Table. 4. The duration of a conventionally bright day ΔTRz when calculating TLc was taken equal to 8 hours for the winter season, 10 hours for the autumn season, and 12.5 hours for the spring and nesting seasons.

Calculations were carried out for the following values of WPP parameters and characteristics of Buteo buteo birds: maximum blade width d=4.1 m, maximum angular rotation speed of the wind wheel ϖ=14 rpm, wind wheel radius R=67 m, hub radius $TR0$=3 m, angle between the chord of the blade section and the plane of the wind wheel $T\gamma$=300, bird length $L1j$=0.54 m, wingspan $l2j$=1.2 m, flight speed 11.6 m/s. The probability of a bird collision with the blades, calculated by the formula (8) in the case of its flight through the wind wheel, is 0.19.

The number of collisions during one year of WPP functioning, calculated by the formula (7) for the collision probability Pj=0.19, taking into account the data in Table 4, equals 3.7 for the spring and 3.0 for the autumn migration season. The total number of collisions was 6.7.

Table 4. Duration of observations TRz, a number of conditional light days ΔTRz in the season and a phase of the life cycle of birds TLc in hours.

Cycle of observation	TRz, hour	TRz, sec	ΔTRz	TLc, days	TLc, hour
Migration in spring	13	46800	12,5	85	1062,5
Nesting	22	79200	12,5	90	1125
Migration in autumn	15	54000	10	100	1000
Winter season	13	46800	8	90	720
Total	63	226800		365	3907,5

Monitoring the territory of the wind park has shown that birds of the species Buteo buteo are found at different altitudes in all seasons. The total number of Buteo buteo birds that were found in the territory of the wind park at all altitudes was 16. One bird was registered outside the RZ in winter, seven – during the spring migration period (2 in the RZ and 5 outside it), three – during the nesting season and five – in autumn (2 in RZ and 3 outside). It can be assumed that, theoretically, in the risk zone of interaction with turbines, birds could appear not only in spring or autumn, but also in winter and nesting periods. Therefore, the registered number of birds in RZ can equally be attributed to any season. In this case, the same formula (13) is valid, but due to the different duration of the bird's life cycle TLc and the duration of the monitoring time $TRisc$, the results will not be the same. The calculated number of collisions during one year of WPP functioning turned out to be 5.6 specimens, which practically coincides with the calculated value in the first case.

Combining the latest data with previously obtained results, which take into account seasonal differences, we can assume that the most reliable anticipation is the range of values 5.6÷6.7. It is interesting to compare the obtained assessment of the interaction of birds with turbines with the anticipation made in 2017 (Osadchyi V. et al.) which was based on the results of WPP monitoring, carried out in accordance with the recommendations of the Scottish Natural Heritage Foundation, 2014. The anticipated number of collisions per one year of WPP functioning according to the data of the mentioned above research work was about 6.5 birds. the observer is located.

4 Conclusions

The Birds2 information system has been developed to ensure the analysis of information, based on the results of monitoring the wind park's territory using the route census method. The program code is compiled on the basis of Windows Forms technology in the Microsoft Visual Studio Community 2019 software environment. The main database contains 48 fields, reflecting the results of monitoring of birds' behavior in the wind park and processing the initial data: year, month and day of observation, an identifier that binds coordinates of the registered bird to the point on the Google-map, time of observation day, observation duration for the selected observation day, bird species, number of birds of this species, type of movement and presence of birds in the observation site, flight altitude, flight speed, direction of flight, coordinates of a point of registration of birds on a Google map, average number of birds flying over the territory of the wind park at a given time and other parameters.

The designed program differs from previously developed information systems in the research works [1] [21] by the ability to identify a number of characteristics of birds of the transit type, which are necessary to anticipate their collision with turbine blades:

• coordinates of points of intersection of the bird's flight path with the perimeter of the wind park or observation site,

• length of the bird's flight path over the territory of the wind park,

• average number of birds, flying over the wind park's territory at a given time.

The analysis of the distribution of birds in the territory of the "Primorsk-1" wind power plant is carried out according to the types of migration (forage, transit, nesting, ground), direction of flight and altitude characteristics. The total number of registered birds was 8927 specimens of 72 species, of which 802 specimens of 11 species were of the transit type, 2511 specimens of 32 species were of the forage type, 5614 specimens of 60 species were on the ground (ground type). Most birds (63%) belong to the ground type. In the forage group 28% of birds, 9.0% of birds were flying in transit. The greatest activity of birds is manifested in the autumn migration season, when the transit group accounts for 77% of all annual transit flights. The proportion of birds of forage and ground types, registered in autumn, is 68% and 74%, respectively, of the total number of birds registered in autumn. In the group of ground birds, the overwhelming majority of specimens belong to the period of autumn migration (4141 or 74%). The least was registered in the winter season (317 birds or 5.6%).

A mathematical model has been developed for analyzing the interaction of birds with turbines using the results of monitoring the territory of wind power plants using the route census method. The model makes it possible to obtain information on the probability of collisions of different species of birds with wind wheels and number of collisions with turbines, depending on the flight characteristics of birds, parameters of wind parks and observation conditions in different seasons. In the risk zone of birds' interaction with turbines, 4 birds of the same species Buteo buteo were registered. The probability of a single bird's collision, when passing through the wind wheel, is about 0.19. The calculated number of collisions of birds with turbines during one year of "Primorsk-1" wind park functioning is within the range of 5.6÷6.7 specimens.

Study of influence of alkaline component type on pH value and properties of alkali activated concretes containing basalt rock

Oleksandr Kovalchuk[1], and *Victoriya* Zozulynets[1,*]

[1]Kyiv National University of Construction and Architecture, Scientific Research Institute for Binders and Materials, 31 Povitroflotskyi Ave., Kyiv, 03037, Ukraine

Abstract. The paper discusses the questions of alkalinity changes in alkali activated cement-based materials at different stages of hardening. It was shown that use of alkali activated cement with dry alkaline component ("all-in-one system") in the presence of basalt rock leads to the immediate decrease of pH value and strength drop of the material. On the other hand, using alkaline component in the form of alkaline solution provides almost normal hardening of systems. Taking into account obtained results a methodology of changes in concrete mix design was proposed. In general, for different cement systems under study pH value varies from 8.5 to 12 reflecting on the materials structure formation processes and strength gain. Shrinkage of the systems was within the ranges 0.3…0.6 mm/m at 28 days age and 0.3…0.5 mm/m for different systems. Absence of expansion witnesses about compensation of ASR results and normal structure developments processes in the material comparing to OPC.

1 Introduction

Nowadays a question of widening of raw materials base became very sharp [1-2], including materials for cement and concrete production [3-5]. Permanent rising of prices on traditional high-quality aggregates leads to the search of chipper ones, but at the same time the less qualified materials [6-8]. Between aggregates in this category there is a high possibility to have active grains (active silica) [9-1], able to participate in reaction with cement matrix and leading to the problems [12-14], some times – technogen accidents [15-17].

Problem of alkali-silica reaction (ASR) of aggregates in concretes is also critical from the point of view of absence of such tests in the quality assurance procedures of the most concrete and concrete constructions manufactures and determination of alkaline corrosion appearance is possible only at the stage of exploitation of construction, when it is to late to provide any actions.

Problem of loses in quality of aggregates and rise of their activity taoks a top rate [18-20]. The point is that shift to the coal use in the portland cement clinker manufacture results in increasing of Na and K compounds in the cement [21-23]. That fact together with increasing of aggregates activity provides appearence of destructive processes in concrete directly in exploitation period [24-26]. In the body of concrete appears reactions «alkalis – active silica » (ASR) [27-29], leading to the formation in the hardened concrete pores new formations, exceeding volume of the pore [30-32]. These formations further leads to the internal stresses in the concrete and may lead the increased leaching of the hardened stone and development of destructive processes [33-35].

Results of the studies [36-38] shows that there are some ways to ASR development in concrete by using active mineral aggregates [39-41], which makes it possible to regulate and control ASR processes development, appearing because of thise reaction and make it constructive [42-44]. The most effective systems in this case are alkaline cements [45-47], which make it possible to change ASR process mechanics from destructive to constructive, shifting in time moment of to the initial stages of structure formation and thus not creating possibility to have destructive processes [48-50].

At the same time, provided investigations studies mostly use of alkali activated cements by two component technology (alkaline component is in the liquid form). Such systems are effective enough, but application of this technology is complicated and far from the ideal [46, 47]. The modern technologies in construction requires application of alkali activated cements in the dry state, « all-in-one » system), which are simply mixed with water.

The problem of such cement application together with active aggregates is that alkaline solutions (by the old technology) have much more alkalis in the system [49], and in the single component cement present alkalis content could be not enough for compensation of negative influence of active aggregate. Use of the extra alkalis on the other hand in dry cement system also is dangerous because of possibility of high leaching rates of material an development of destructive processes [51].

The aim of the study to investigate changes in pH value for different cement systems and to study optimal alkaline component content in the cement system.

2 Raw materials and methods

To investigate the processes of inner corrosion of the slag alkaline concrete the basalt rock has been selected as aggregates. Quartz sand was taken for reference. Chemical composition of the rocks is given in Table 1.

Table 1. Chemical composition of rocks

Oxide	Oxide content, % by mass, in aggregate
	Basalt
SiO_2	50.42
Al_2O_3	14.0
Fe_2O_3	6.14
FeO	8.37
TiO_2	2.66
MnO	0.243
CaO	8.04
MgO	5.56
P_2O_5	0.316
K_2O	0.71
Na_2O	2.27
SO_3	0.07
Σ, %	99.57

For a complex estimation of durability of the slag alkaline concretes with alkali-reactive aggregates, the strength kinetics was investigated, for which a standard procedure was used.

Ground granulated blast furnace slag with a specific surface 450 m^2/kg (by Blaine) was used in the experiments. Chemical composition of the slag is shown in Table 2.

The graded aggregates were in used in the experiments. The quantities of aggregate retained on the No 2.5 mm, 1.25 mm, 0.63 mm, 0.315 mm and 0.14 mm-sieves were 20 % by weight of each.

The beam specimens (25×25×254 mm) made of slag alkaline concretes of equal consistency with a flow of 170+/- 5 mm, according to procedure specified by the DSTU B V.2.7-186, were prepared using a vibrating table. The cement to aggregate ratio was taken as 1: 2. Used as alkaline component were the Na_2CO_3 in dry state and soluble glass with density 1250 kg/ cub m.

Alkalinity of the hardening systems (pH) was determined after 1, 2, 3, 4, 5 i 24 hours of hardening by measuring properties of 10% water solution at pH-meter PL-700al (pH/ORP/Conductivity/TDS/Salt/DO/Temp).

As a reference material was taken OPC Grade 42.5 with a specific surface 320 m^2/kg by Blaine.

Also for reducing alkaline corrosion value of concrete the active mineral admixture was taken (represented by metakaolin) in the quantity 10% (MK).

Length of the specimens was measured using a pointer-type indicator with a scale factor of 0.01 mm.

Between 2 to 4 hr. before the next measurement the specimens were removed from the thermostat and allowed to cool in the environment with T=20+/-2 ºC.

Table 2. Chemical composition of blast furnace slag

Oxides	Oxide content, % by mass
	No 1
SiO_2	38.6
Al_2O_3	6.50
CaO	48.50
MgO	5.40
MnO	-
FeO	0.36
SO_3	1.99
TiO_2	-
P_2O_5	-
K_2O	-
Na_2O	-
Σ, %	101.35

Linear deformations of the slag alkaline concretes were compared with those of the reference specimens made with sand. The linear deformations of the slag alkaline concretes made with alkali- reactive aggregates were studied using a basic blastfurnace slag as the most typical representative reflecting peculiarities of the processes of hardening [51].

3 Results and discussion

Traditionally during mix design of alkali activated cements alkaline solutions of sodium silicates and carbonates are using as an alkaline component. In our case, to determine limit points of alkali activated cements were studied of the cements using soluble glass (SS) with density 1250 kg/m^3 with silicate modulus 2.6.

Variation of pH value for different cement compositions in paste are shown in Table 3 and at the Figure 1.

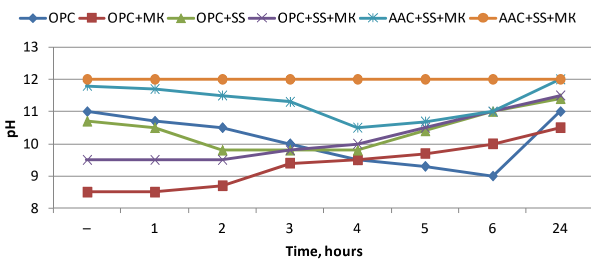

Fig. 1. Variation of pH value depending from content of the alkaline component, represented by alkaline solution.

Analysis of the results shows that at initial stages the highest pH value have alkali activated cement using soluble glass, regardless metakaolin admixture.

Use of OPC also provides high alkalinity of media (pH=11). However, it has regularity to rapidly decrease in time and at the age of 6 hours it is pH=9.Then at 1 day age is returns to pH=11. Such behavior could be explained in that way: high alkalinity at initial stage provided by calcium hydroxide further decreasing via reaction with active SiO_2, which is leaching from the aggregate. Then, reaching limit point in the system, content of soluble silica in the media is reducing and content of portlandite is rising because of continuation of clinker minerals reaction continuation. This creates proper conditions for hardening and strength gain and this is explaining absence of negative influence of active aggregate on material exploitation properties at initial stages of hardening and exploitation.

Table 3. Variation of pH value in alkali activated cements using alkaline solutions as alkaline component and referenced materials.

Time, Hrs	pH					
	AAC	AAC+MK	AAC +SS	AAC +SS+MK	AAC +SS+MK	AAC+SS+MK
–	11.0	8.5	10.7	9.5	11.8	12.0
1	10.7	8.5	10.5	9.5	11.7	12.0
2	10.5	8.7	9.8	9.5	11.5	12.0
3	10.0	9.4	9.8	9.8	11.3	12.0
4	9.5	9.5	9.8	10.0	10.5	12.0
5	9.3	9.7	10.4	10.5	10.69	12.0
6	9.0	10.0	11.0	11.0	11.0	12.0
24	11.0	10.5	11.4	11.5	12.0	12.0

Introduction of metakaolin admixture to the OPC system provides decreasing of total alkalinity of the system at initial stage to pH=8.5. Further pH is rising slowly up to 10.5 at 6 hours age. Such peculiarities of hydration and structure formation processes provide low strength gain of OPC systems with active mineral admixtures using active aggregates, limiting application areas for such materials.

Introduction of metakaolin into the alkali activated cement composition using soluble glass as an alkaline component also decreases a while total alkalinity of the system at initial stage (pH reduces to 11.8 comparing to 12). Further alkalinity reduces for 4 hours, reaching pH=10.5. After that alkalinity rises to pH=11at the age of 6 hours and reaches pH=12 at 24 hours age. Such high pH value in alkali activated cement using soluble glass at different stages provides possibility to use active aggregate without loses in strength properties.

Alkali activated OPC has low pH value at initial stage – 10.7. Further alkalinity of the system is rising and reaches pH=11 at 6 hours age and pH=11.4 at 24 ours age. Such behavior and differences from processes in OPC could explain by shifting of alkalinity source from calcium hydroxide to sodium compounds because of decreasing of total basicity of new formations (hybrid compounds). This makes it possible to predict slow strength gain at initial stages and further rapid increasing of strength after 1 days of hardening.

Introduction of metakaolin provides decreasing of initial pH to 9.5 with stability during 2 hours and rising rapidly to 11 at 6 hours age and 11.5 at 24 hours age. Such behavior could be explained by presence of high alkaline ions source in the system and bonding of active silica from the basalt rock composition at initial stages. This makes it possible to predict a little bit slow hardening at initial stages and reaching of normative properties at 28 days age.

Thus a way, from the point of view of high alkalinity of media at initial stages the best systems are alkali activated OPC with and without metakaolin admixture. They have high alkalinity rates as at initial stages (pH=12 and 11.8 respectively), so as at the age of 1 day (pH=12 for both systems).

Alkalinity of OPC systems is a little bit lower (pH=11) at initial stage, decreasing at initial stages of hardening and than stabilizing at the level pH=11 at the age of 1 day providing source for normal hardening and structure formation. Introduction of metakaolin decreases total alkalinity at initial stage to 8.5 with slow rising to 10 at the age of 6 hours and 10.5 at 28 days age. Such process of structure formation is potentially problematic for strength properties.

The worse system from the high pH value at initial stage is alkaline OPC. Low pH of the system without metakaolin (10.7) with following stabilization at pH=11 (at 1 day age) provides slow strength gain, and introduction of metakaolin decreases pH to 9.5, storing for 2 hours and rising to 11 at 6 hours age.

Also it should be mentioned that for alkali activated cement system with soluble glass the pH value is 12 at all stages regardless of metakaolin introduction.

On the other hand, the modern world needs single-component premixed cements. Alkaline component of such alkali activated cement was represented by sodium carbonate (soda ash).

To determine optimal content of alkaline component alkali activated cement (AAC) type I according to DSTU B V.2.7-181 was used with additionally alkalis (sodium carbonate) in the quantity 2, 4, 6, 8 i 10% by mass. Initial content of alkaline component in the cement was 4.5% (2.5% calculated on Na_2O). Thus, maximal alkalis content in the cement system was 7.54% by mass calculating on Na_2O. Such significant increasing of alkalis content in the system was directed for compensation of negative influence of active aggregate on structure and service characteristics of material. Test results are given in Table 4 and shown on Figure 2.

Table 4. Influence of alkaline component content on total alkalinity of cement paste media.

Time, hrs	pH					
	AAC	AAC +2% soda ash	AAC +4% soda ash	AAC +6% soda ash	AAC +8% soda ash	AAC +10% soda ash
–	10.0	10.0	11.0	11.5	11.7	11.7
1	9.0	10.0	11.0	11.5	11.5	11.5
2	9.0	9.5	10.5	11.0	11.5	11.5
3	9.0	9.2	10.5	11.0	11.2	11.2
4	8.7	9.0	10.2	11.0	11.2	11.2
5	8.7	9.0	10.2	11.0	11.0	11.2
6	8.5	8.7	10.2	11.0	11.0	11.0
24	7.5	7.8	7.8	11.0	11.0	11.0

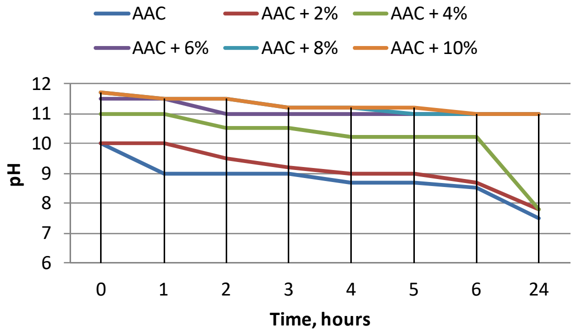

Fig. 2. Variation of pH value depending from content of the alkaline component, represented by dry salt.

Analysis of obtained results shows that using active aggregates alkalinity of the system if decreasing even at initial stage. Without additional alkaline component at initial stage pH is 10 and rapidly dropping. From the point of view of total; alkalinity of the system optimal content of additional alkaline component is 6% of soda ash that provides totally 5.4% of alkalis in the system calculation on Na_2O.

Obtained results confirms predictions that using active aggregates with dry alkali activated cement mix the traditional alkalis content is not enough. This could be explained by reaction between silica acid, leaching from the basalt rock, and alkaline component, resulting in sodium hydro silicates formation. Such process is not destructive. However, decreasing of total content of free alkalis in the media and pH value leads to slowing of structure formation processes in alkali activated cement of stop it in general. That is why for storing total alkalinity of the system the additional alkaline component content 6-6% by mass of the cement is required.

Obtained results make it possible to propose method of compensation of negative influence of active aggregates on concrete basing on single component alkali activated cements. This will provide necessary density of alkaline component in the cement media and create conditions for hardening.

Compressive strength of the concretes under study is shown in Table 5 and on Figure 3.

Table 5. Strength properties of fine grain concretes using basalt rock as an aggregate

№	Composition	Compressive strength of fine-grain concrete, MPa, at the age, days			
		2	7	28	90
1	OPC+ Soluble glass	18.8	28.4	46.8	58.4
2	OPC+ Soluble glass + 10% MK	13.8	28.4	70.8	81.5
3	AAC type I	10.8	29.4	418	48.4
4	AAC type I +10% MK	5.8	28.4	42.3	48.8
5	OPC Grade 42.5	8.8	23.4	41.2	47.3
6	OPC Grade 42.5	5.2	20.1	40.2	43.1

Analysis of obtained results shows that systems with metakaolin are a little bit weaker than systems without admixture. The best strength properties have systems using alkaline OPC (with soluble glass) regardless using metakaolin. This could be explained by presence of high sodium silicate ions in the system because of soluble glass use.

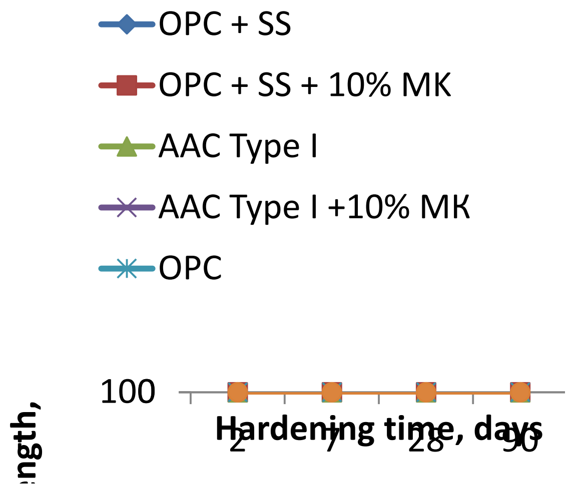

Fig. 3. Variation of compressive strength of fine grained concretes using basalt rock as an aggregate.

The systems mixed with water are characterized by almost equal strength at 28 days age and showing strength gain at further ages. This could witness about constructive development of structure formation processes and absence of huge destructive processes in the material at the stages under study.

Fine grained concretes on AAC type I basis are showing equal strength properties at 2 days age comparing to those on OPC basis. At the age of 7 days characteristics of alkaline concrete is higher than characteristics of OPC based concretes, becoming equal at 28 days age and a little bit higher at 90 days age. That is witnessing about enough potentials of properties development for the systems on AAC basis.

At the same time, strength properties are not expressing well development of destructive processes caused by ASR in concretes. The more informative are study of shrinkage (expansion) deformations of the systems under study. The basis characteristics were taken immediately after remolding, and then characteristics were fixed at 2, 7, 28, 90 and 180 days of hardening. Tests of deformation were performed by measuring tool with indicator IP-04 with accuracy 0.01 mm. Results of the study are shown in Table 6 and on Figure 4.

Table 6. Shrinkage deformation of fine grained concretes using basalt rock as an aggregate

№	Composition	Shrinkage deformations, mm/m, at the age, days				
		2	7	28	90	180
1	OPC+ Soluble glass	–0.23	–0.45	–0.63	–0.55	–0.51
2	OPC+ Soluble glass + 10% MK	–0.30	–0.49	–0.61	–0.49	–0.36
3	AAC type I	–0.21	–0.33	–0.44	–0.43	–0.40
4	AAC type I +10% MK	–0.15	–0.26	–0.31	–0.33	–0.32
5	OPC Grade 42.5	–0.25	–0.41	–0.50	–0.44	–0.40
6	OPC Grade 42.5	–0.19	–0.27	–0.41	–0.30	–0.23

Analysis of the results shows that all materials under study are characterized by shrinkage deformations in all test area. It should be mentioned that highest shrinkage for sure have compositions using soluble glass, and the lowest – alkali activated cement AAC type I. That could be explained by higher gel phases in the systems with soluble glass, which are much lower represented in the systems with dry alkaline components.

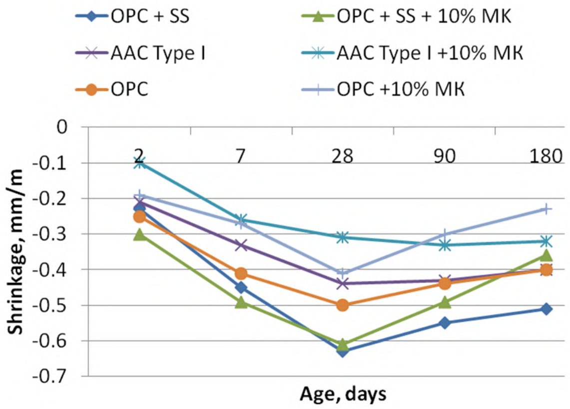

Fig. 4. Shrinkage deformation of fine grain concrete using basalt rock as an aggregate.

It has to mention that for all systems under study shrinkage is reducing with time, witnessing about development of expansion processes via ASR.

The best systems were alkali activated cement with and without metakaolin admixture, which are characterized by spline shrinkage deformation development and insignificant function changes by aggregates corrosion processes gain and expansion.

The present results are expressing specimens hardening in normal conditions. The further studies will be focused on the use of express methods of shrinkage investigation.

Conclusion

1. It is shown that the best cement composition from the high pH value at the initial stages of hardening are alkaline OPC using soluble glass as an alkaline component as in initial state, so as using metakaolin admixture (pH=12 and 11.8 respectively), keeping the rate at the age of 1 day (pH=12 for both systems). Alkalinity of OPC systems is lower (pH=11) at the initial stage, reducing at the initial terms and stabilizing at pH=11 at the age of 1 day, providing normal condition for hardening. Introducing a metakaolin decreases pH to 8.5 with rising to 10 at the age of 6 hours and 10.5 at the age of 1 day. The worth system is alkaline OPC. Low initial alkalinity (pH=10.7) with following reducing to the 10 at the age of 1 day provides low strength gain, and introduction of metakaolin admixture reduces pH to 9.5, storing it for 2 hours and further rising to 11 at the age of 6 hours.
2. Use of active aggregates could complicate of stop structure formation processes in alkali activated cements with dry alkaline component. It is shown that traditional alkalis content in the cement is not enough for normal structure formation processes, and total alkalinity of the system drops at the initial stages and keep reducing in time. Optimal content of alkalis in the system is 6-8%, providing pH 11.5-11.7, and also pH storage in time (up to 11 within 4-24 hours). From the strength point of view the best systems are alkaline OPC as it is, so as with metakaolin admixture (46.8 and 70.8 MPa at the age of 28 days respectively).
3. From the shrinkage point of view the best systems are alkali activated cements with and without metakaolin admixture (-0.44 and -0.31 mm/m respectively at the age 28 days), showing also lower shrinkage at further ages. That could witness about slowing of alkaline corrosion of aggregate processes in the material.

Authors express their gratitude to the Ministry of Education and Science of Ukraine for financial support of the research, which was performed in the framework of budget funding 4DB-2019.

Abstract. Article is devoted to the investigation of suitability of low carbon Roman cement for restoration and finishing works. The history of the development of Roman cement as a natural hydraulic binder, which was commonly used to decorate building facades in the 19th and early 20th centuries, is presented. The properties of mortars based on Roman cement make it an excellent product for architectural restoration and conservation, as they are characterized by fast setting, high porosity typical for lime mortars, high resistance to weather conditions, high initial strength. At the same time, due to the high surface activity and increased water demand for cement, with the age of hardening, shrinkage deformations can develop, which leads to the formation of main cracks on the surface of the products. It is shown that the addition of gypsum is an effective regulator of the setting time of Roman cement and contributes to an increase in the strength of the cement paste. Analogs of Roman cement based on multicomponent cement binders modified with plasticizing and air-entraining additives are presented.

1 Introduction

In accordance with the requirements of the Paris Agreement under the UN Framework Convention on Climate Change (UNFCCC) to regulate measures to reduce carbon dioxide emissions in construction, low-carbon eco-cements will become increasingly important [1,2]. As a result of the ecological action of the cement industry in the direction of sustainable development, such low-carbon cements due to the choice of appropriate combinations of components become an alternative to conventional Portland cements [3-5].

In this regard, a significant practical interest is Roman cement, which is one of the stages of development of the technology of binders and has been widely used since the early nineteenth century. In 1796, James Parker [6] for the first time obtained a new brown cement, reminiscent of ancient Roman lime and pozzolana powders, and called it Roman cement when firing marl limestone with a significant content of clay impurities (30-35%) taken from the slopes of Mount Kent (England). French chemist Louis Vicat noted that the calcined material (clinker) with a high content of Al_2O_3 and SiO_2 has hydraulic properties. According to H. Kühl's [7] classification, the term "Roman lime" (Roman cement) covers a group of binders that are not considered burnt clinker, but also do not belong to lime due to the low content of free CaO.

At the end of the 19th century (1890), the Journal of the Technical Society of Cracow published a definition of Roman cement, which stated that this material was obtained by not roast-sintering clay-limestone marls with subsequent grinding to a powdery state. The most famous English Roman cements were made of marl limestone with inclusions of clay or raw materials from Cretaceous or Jurassic formations. In France, marl deposits from the Jurassic regions of Burgundy and chalk near Grenoble were used. The main centers of Roman cement production were also Switzerland, Germany, the Czech Republic and Galicia. In the Western region of Ukraine (XIX-XX centuries) building mixes on the basis of Roman cement were widely used, namely not far from Lviv workshops were created for the production of various standard architectural details for finishing buildings on the basis of Roman cement. This material was called "Lviv Stone", which is very similar in texture and composition to natural stone, which was proved during a survey of existing architectural monuments in Lviv by specialists-restorers in recent years. However, after the end of World War I, Roman cement was rarely used, and later the technology of its production and finishing techniques were forgotten [8].

Today Roman cement is of considerable practical interest as a natural hydraulic binder for repair and restoration works. As part of the European project EU-project ROCARE "Roman cement for the restoration of architecture to new high standards" based on research by

* Corresponding author: msanytsky@ukr.net

foreign scientists (J. Weber, C. Gosselin, R. Kozlowski, H. Szeląg, A. Garbacik) in Austria and Poland it is established research-industrial production of Roman cement, restored the technology of its manufacture, expanded the range of products based on it and created the possibility of using the material in the restoration market [9-13].

When mixed with water, Roman cement quickly setting and hardening compared to Portland cement. This is due to the formation of calcium hydrosilicates C-S-H (B), as well as tricalcium hydroaluminate C_3AH_6 and hydroferrites C_3FH_6. To regulate the properties of the composition of Roman cement during grinding, could be added up to 5% gypsum of various modifications and up to 15% of active mineral additives. Roman cement-based mortars are characterized by rapid hardening, high porosity, which is also characteristic of lime mortars. Plasters based on such binders do not retain moisture in the walls of the building, which prevents the formation of cracks [14-16].

Roman cement is also used for the manufacture of paints for renovation of the surface of plasters and other decorative elements. Such paints are suitable for decoration, restoration and aesthetic integration of the facade and architectural elements, especially when applied to decorative elements with a wide range of details in the form of carvings or in cases where it is impossible to perform a thin layer (2-3 mm) of plaster. However, the lack of proper raw materials significantly complicates the production of Roman cement, and low production capacity leads to a significant increase in its cost [17].

At present, the production of Roman cement is established at the research and production plant of the Institute of Ceramics and Building Materials (Department of Glass and Building Materials in Krakow, Poland). Burning of Roman cement clinker takes place in rotary kilns measuring 1.25x16 m at a temperature of 800-900°C. During the burning of raw materials (natural marls) there is a dissociation of calcium and magnesium carbonate, which promotes the active passage of reactions in the solid state with the formation of the main phases of Roman cement - calcium silicates β-C_2S (belite), calcium aluminates CA and $C_{12}A_7$, ferrite C_2F. High burning temperature (above 1000°C) leads to overheating of raw materials with the formation of hydraulically inert mineral gehlenite C_2AS. However, the low burning temperature does not provide a full degree of material synthesis [18, 19].

In the production of Roman cement, the raw material mixture is burning in the form of granules. The firing temperature in the inner part of the clinker and on its surface is not the same, which prevents the achievement of an equilibrium reaction. The reaction between silica and alumina occurs only in areas of maximum burning temperatures. Highly reactive phases such as CA, $C_{12}A_7$, formed on the surface of clinker granules without the presence of glass phase, determine the rapid hardening and strength in the early stages, and with age of hardening, the increase in strength occurs due to hydration of the belite phase. Fine binder also provides pozzolanic reaction in addition to hydraulic that allows improving construction and technical properties of Roman cement (Fig. 1). The hydration of the cements studied was shown to comprise two distinct stages. The immediate setting and early strength is due to the formation of calcium aluminum oxide carbonate (or sulfate) hydroxide hydrates. The development of long-term strength is brought about by the formation of calcium silicate hydrates [20].

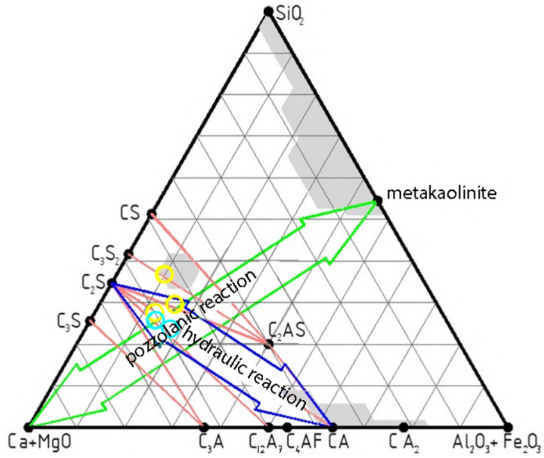

Fig. 1. Hydraulic and pozzolanic reactivity of Roman cement (according to Wolter [20]).

Roman cement is characterized by increased water consumption and rapid hardening as well as shrinkage [21, 22]. There are rapid and slow hardening types of Roman cement. For Roman cement with the initial hardening time not more than 15 minutes, the compressive strength should be not less than 6.0 MPa.

The addition of lime does not retard Roman cement hydration, therefore retardation of Roman cement is essential in hybrid mortars. Lime permits fine control of mortar (workability, workable life, strength). This results indicate a wider potential for render applications in general. If the Roman cement is retarded by means of a pre-hydration process, hybrid mortars can be produced with improved workability and workable life as well as permitting the fine control of strength and moisture transport [23].

Roman cement's compositions modified by chemical and mineral additives have been proposed [24]. Plasticizers and hardening accelerators were chosen and used that allowed rising the durability up to 35 MPa relatively. Superplasticizers and air-repellent additives help to reduce the amount of water, increase water resistance and durability. Mineral additives like slag, zeolite tuff and clay dust were chosen and used that rise the strenght from 22 to 28 MPa. In this case, Roman cement with zeolite-containing mineral additive in a dosage of 15-16%, shows maximum strength.

On the other hand, of considerable practical interest is the development of substitutes for Roman cement with appropriate physical and mechanical properties and plasters based on them. With the introduction of mineral additives of different types, it is possible to obtain a low-CO_2 multicomponent cements [25-27]. To accelerate the processes of early structure formation, it is advisable to use alkaline activation [28, 29]. Of particular note are decorative multi-component alkali activated cements for restoration and finishing works, which are chemically analogous to Roman cement [30]. Such multicomponent cements, modified with complex admixtures plasticizing and air-absorbing action, have comparable or even better performance compared to Roman cement and allow allow to use them successfully in making plasters, mortars. for restoration, finishing works and decoration of facades. Promising direction for improving the properties of multicomponent binders is nanomodification in combination with nanosilica [31, 32].

At the same time, Roman cement plays an important role in the technology of restoration work. Therefore, the task is to study the features of the processes of structure formation and the formation of the properties of Roman cement for its suitability and increasing the operational properties.

2 Materials and methods of research

2.1 Materials

Roman cement was used in experimental research (IMMB, Poland). The chemical composition of Roman cement is respectively 51.1 wt.% CaO; 33.0 wt.% SiO_2; 8.54 wt.% Al_2O_3; 2.34 wt.% Fe_2O_3; 2.01 wt.% MgO; 1.33 wt.% K_2O; 0.4 wt.% Na_2O; 0.87 wt.% SO_3; 12.33 wt. % LOI.

As can be seen from Fig. 2, on the X-ray powder diffraction patterns of non-hydrated Roman cement, in addition to the lines of basic clinker minerals β-Ca_2SiO_4 (β-C_2S) and $CaAl_2O_4$ (CA), lines of calcite $CaCO_3$ (d/n=0.303; 0.277; 0.208; 1.912 nm), quartz β-SiO_2 (d/n=0.424; 0.334; 0.249; 0.228 nm) and gehlenite $Ca_2Al(Al,Si)O_7$ (d/n=0.285; 0.176 nm) are additionally displayed. The content of SiO_2 and $CaCO_3$ is 10 and 25 wt.%, which indicates the incomplete nature of the reactions of solid-phase synthesis of clinker minerals of Roman cement.

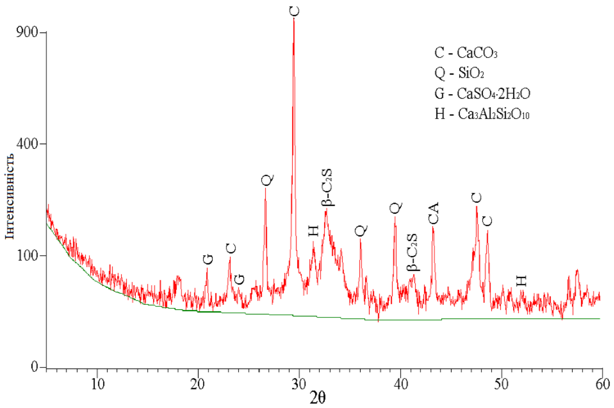

Fig. 2. X-ray powder diffraction patterns of non-hydrate Roman cement.

Roman cement is a decorative binder (the reflection coefficient of the degree of whiteness is 60%).

2.2 Methods

Determination of physical (average density, porosity, water absorption), physical and mechanical properties of Roman cement was carried out according to standard methods. The study of the phase composition of cement hydration products was performed using a set of modern physical and chemical methods of analysis: X-ray diffractometry (DRON-2.0, Siemens D5000), differential thermography (OD-1500Q), and mercury porometry (Autopore II 9220). The chemical compositions of cements and mineral additives were determined by an ARL OPTIM'X X-ray spectrometer. Calorimetric studies of hydrated cement samples were performed using a Zwick Roel calorimeter. Philips XL30 ESEM-FEG and REM-106I scanning electron microscopes were used to study the morphology of the paste surface on the basis of decorative cements and plasters. Fineness of cementitious materials was characterized by the spesific surface area using the Blaine air permeability test. Particle-size distribution was studied with the help of laser high-resolution particle size analyzer Mastersizer 3000.

3 Research results

It was established by the method of laser granulometry (Fig. 3), that for Roman cement (SSA=800 m^2/kg; A_{008}=4.0%) the content of fractions Ø1; Ø10; Ø20 and Ø60 μm is 14.5; 48.7; 59.4 and 88.3% respectively. The grain size of D10; D50 and D90 correspond to 0.79; 11.8 and 69.61 μm.

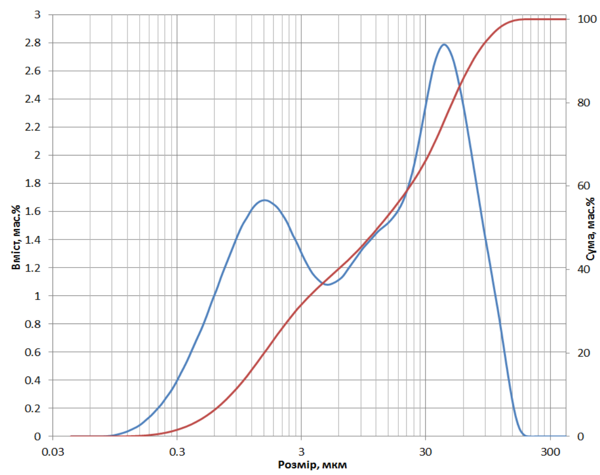

Fig. 3. Particle size distribution of Roman cement.

Based on the granulometric analysis data, the differential surface activity coefficient (K_{isa}) was calculated. This coefficient is defined as the A/V multiplication for a given particle size (ratio of particle surface area to volume, μm^{-1}) by the volume content of each material fraction, based on laser-determined graining data [33]. The K_{isa} value determines the surface activity of a given particle size in the set of cement grains. Thus, the development of the specific surface is determined by the contribution of small fractions and the maximum value of K_{isamax}=10.0 μm^{-1}·vol.% is achieved for the fraction of 0.6 μm, while for the fraction of 42.0 μm with a maximum content of particles (2.8 wt.%) K_{isa} is only 0.43 μm^{-1}·vol.%.

As can be seen from Fig. 4, the contribution of small fractions to the development of the specific surface is decisive. The high dispersion of such particles largely determines their surface energy and leads to a significant water demand of the binder.

Calorimetric analysis (Fig. 5) showed that the Roman cement is characterized by a short induction period (τ=12 min) and low heat of hydration (29.8 J/g), while the exoeffect is 31.6 cal/(gh).

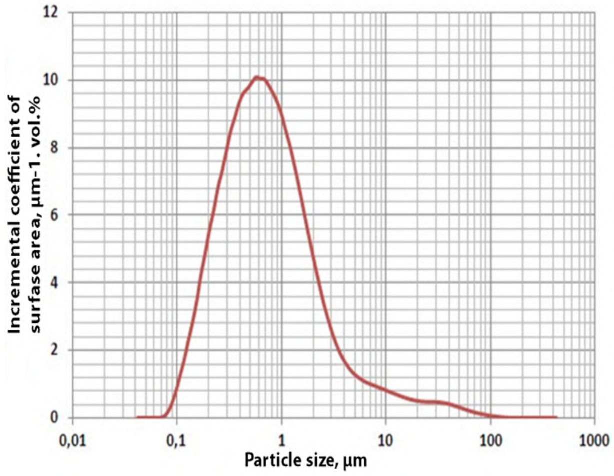

Fig. 4. Differential coefficient of surface activity of Roman cement.

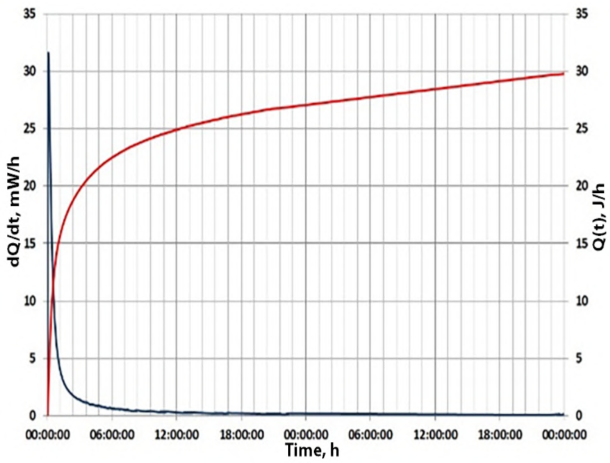

Fig. 5. Kinetics of Roman cement heat release.

Highly reactive phases such as CA, $C_{12}A_7$ determine the rapid hardening and strength in the early stages, and with age of hardening, the increase in strength occurs due to hydration of the belite phase. Initial and final setting time of the cement (water demand - 0.40) is 3 and 8 minutes, respectively, and the strength of the paste after 1; 3; 7 and 28 days of hardening is 4.9; 6.1; 7.6 and 20.8 MPa respectively. For fresh cement-sand mortar (C:S=1:3) based on Roman cement the workability (consistence by flow table) – 115 mm (W/C=1.0); in this case standard compressive strength of 10 MPa is reached.

Roman cement mortars are characterized by exceptionally accelerated hardening time, which causes difficulties in plastering. Addition of 1.0 mass.% citric acid to Roman cement (W/C=0.47; workability – 113 mm) allows to delay initial setting time for 40 min, while the compressive strength after 7 and 28 days is 4.93 and 21.8 MPa, respectively.

In order to establish the physicochemical laws of the formation of the structure and synthesis of the strength of Roman cements, the influence of gypsum was studied. For Roman cement paste, water consistency is achieved at W/C=0.40, initial and final setting time are respectively 3 and 8 min, the compressive strength after 3; 7 and 28 days is 6.1; 7.6 and 20.8 MPa (Table 1). Addition of 5 mass.% gypsum dihydrate can reduce the water consumption by 17.5%, while the initial and final setting time is delayed, and the compressive strength of the paste after 3; 7 and 28 days of hardening increases by 4.5; 4.8 and 2.7 times.

Table 1. Influence of gypsum dihydrate on the strength of Roman cement paste.

Gypsum additive, mass.%	W/C	Setting time, h-m		Compressive strength, MPa, in the age, days				
		initial	final	1	3	7	21	28
-	0,40	0-03	0-08	4,9	6,1	7,6	14,0	20,8
5,0	0,40*	0-20	0-24	4,5	19,4	32,5	38,2	44,5
5,0	0,33	0-16	0-19	10,8	27,5	37,0	49,8	55,6

As can be seen from Fig. 6, the hydration of the Roman cement takes place in two stages: the first is the hydration of the aluminate phase, due to which the Roman cement sets quickly and gains strength in the initial curing period, in the second stage the belite phase provides strength gain at a later curing time. Due to the significant water-reducing effect (ΔW/C=45%) of the Roman cement with the addition of gypsum dihydrate, the strength of the binder after 28 and 90 days of hardening is increased by 2.2 and 2.4 times, respectively, compared to the Roman cement without additives.

This indicates that the use of gypsum dihydrate and retarding additives allows to change the course of the processes of structure formation, which determines further studies of their effect on the phase composition and microstructure of the Roman cement. Peculiarities of Roman cement hydration processes were studied by methods of physical and chemical analysis.

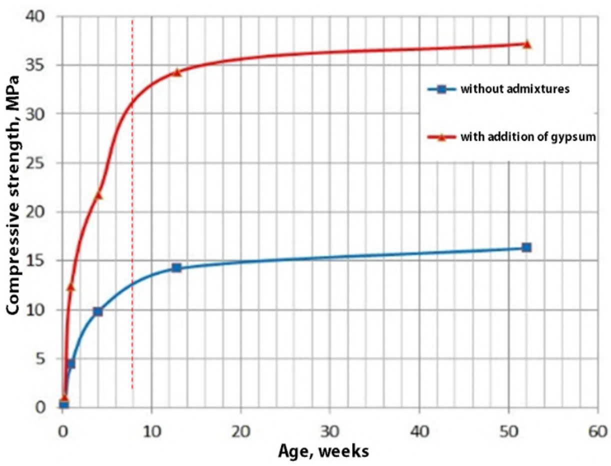

Fig. 6. Strength of Roman cement paste with age of hardening.

After 28 days of hydration, the calcium hydrocarboaluminate lines $C_3A{\cdot}CaCO_3{\cdot}12H_2O$ (d/n=0.761; 0.380 nm) are additionally observed on the diffractograms and the lines of portlandite are practically absent (Fig. 7). For Roman cement paste with the addition of gypsum, the newly formed hydrated phases of etringite (d/n=0.973; 0.561; 0.469 nm) and hydrocalumite (d/n=0.82 nm) are

https://doi.org/10.1051/e3sconf/202128007002

observed. To calculate the degree of hydration, β-C_2S (d/n=0.218 nm) was used as the analytical line. It was found that for Roman cement after 28 days of curing, the degree of hydration is 71.0%.

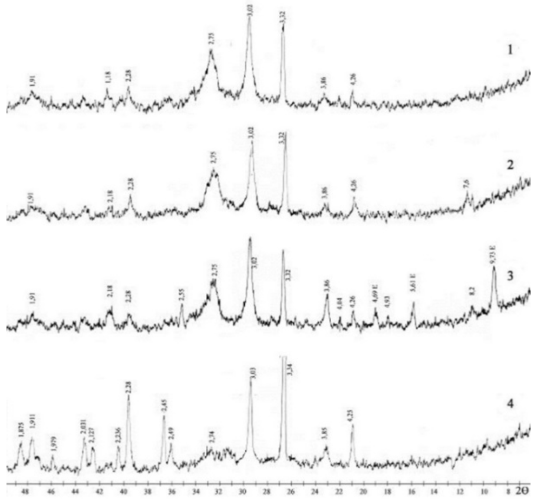

Fig. 7. Diffractograms of hydrated Roman cement paste at 28 days: 1 - non-hydrated; 2 - hydrated without additives; 3 - hydrated with the addition of gypsum; 4 - from a decor element.

According to the thermal analysis (Fig. 8), it was found that for Roman cement with the addition of gypsum, the DTA curve recorded the endothermic effect at 125°C, which corresponds to the release of water from calcium hydrosulfoaluminates. The DTA curve also shows an endoeffect in the temperature range of 600-850°C due to the decomposition of hydroaluminates and calcium carbonate. According to thermogravimetry (TG), the total weight loss during calcination for Roman cement with the addition of gypsum is 34.8%.

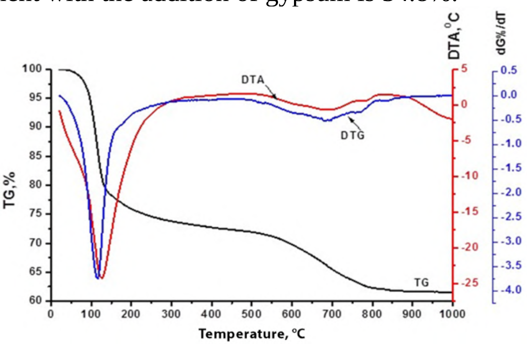

Fig. 8. Derivatograms of Roman cement, hydrated 90 days.

The method of scanning electron microscopy shows (Fig. 9) that the Roman cement, hydrated at 28 days, is characterized by a porous structure with a large number of open capillary pores. The formation of small crystals of calcium hydroaluminates (C-A-H) is observed on the pore surface. The addition of gypsum allows to compact the structure of the Roman cement paste by colmatation the open pores with AFt-phases. According to the data of microprobe X-ray spectral analysis, the relative elemental composition of the pore surface shell corresponds to the main components of Roman cement clinker, mass.%: Ca - 40.59; Al - 16.8; Si - 16.6; Fe - 0.6; O - 36.8. The surface of the pores is formed from the nuclei of crystals, as a result of which the capillary pulling of water and water absorption of the Roman cement paste are reduced.

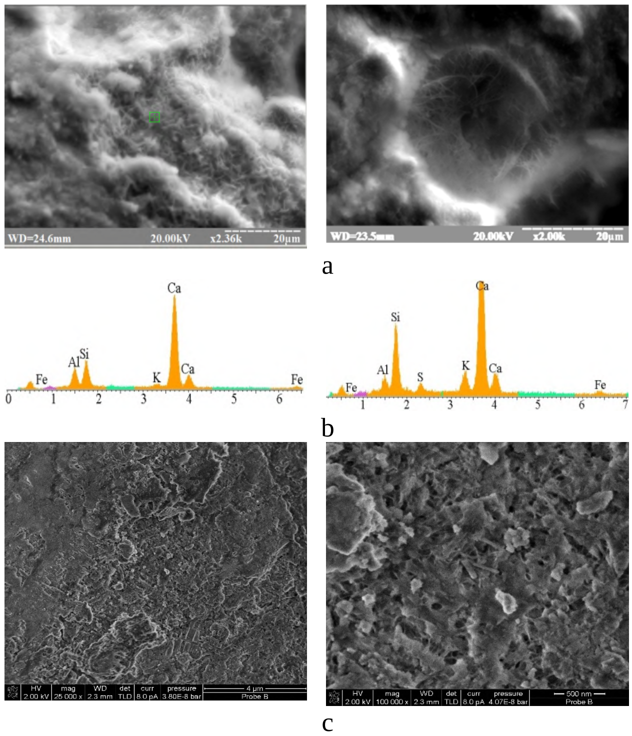

Fig. 9. Microstructure of Roman cement paste: a, c - at 28 and 360 days; b - X-ray spectra from the surface of pore at 28 days.

Roman cement is characterized by significant porosity. Thus, for a paste based on Roman cement without additives, the total porosity is 41.0% (open - 19.0%, closed - 22.0%). Addition of gypsum into the Roman cement allows to reduce the total porosity to 37.78%, while the open porosity is reduced to 11.78% (Fig. 10). [89, 133].

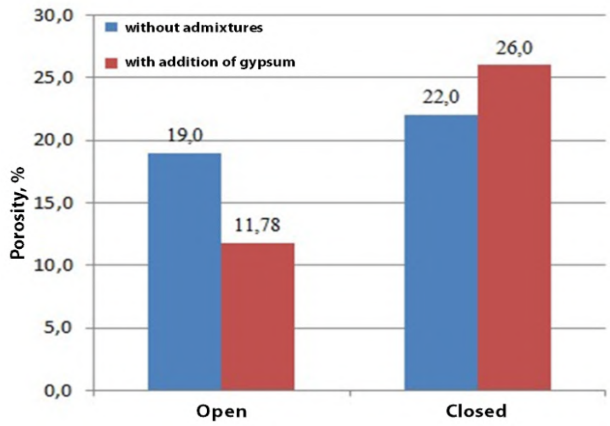

Fig. 10. Open and closed porosity of Roman cement paste.

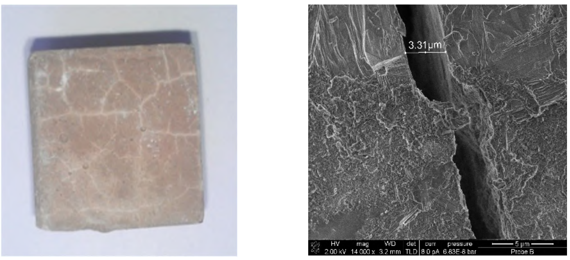
Among the factors that determine the strength of the paste, of particular interest are the processes of destruction of its structure. Visual observations for a sample based on Roman cement (Fig. 11, a) after 1 year of curing show hair cracks covering the entire volume of the sample. The photomicrograph shows (Fig. 11, b) that the destruction of the material can cause main cracks, one of which is characterized by a width of 3.31μm, the formation of which is due to the union of closed scaly submicroscopic micro cracks in the crystalline aggregates and between them, which is the reason of deformations of shrinkage of a Roman cement.



a b

Fig. 11. The nature of the destruction of Roman cement, hydrated for 1 year: a - hair cracks in the sample; b - micrograph of shrinkage crack (x14000).

The peculiarities of chemical and mineralogical composition and high dispersion of Roman cement determine a significant increase in its water consumption, which leads to increased porosity of artificial stone, the formation of various cracks and possible peeling of plaster.

At the same time, despite many of its advantages, Roman cement is currently not widely used, and its production is low-tonnage, which determines its high cost. This is due to the relatively rare deposits of the raw material, which must have fine intergrowths of calcium carbonate and hydraulic components in the correct proportion. In addition, there are currently not enough low heat shaft kilns that are suitable kilns for the production of Roman cement.

4 Conclusions

1. The peculiarities of the chemical and mineralogical composition of Roman cement are revealed and its influence on the processes of hydration and hardening are established. High dispersion (SSA=800 m^2/kg) and surface activity of Roman cement lead to an increase in its water demand.

2. The increased content of the highly reactive aluminate phase (CA, $C_{12}A_7$) in the Roman cement determines the fast setting (initial and final setting time - 3 and 8 min, respectively) and strength in the early stages of hardening; the increase in strength with age of hardening (strength at 28 days is 10…20MPa) is achieved by hydration of the belite phase. After 1 year of hardening, main cracks may develop in the Roman cement paste due to deformation of the shrinkage.

3. The addition of gypsum is an effective regulator of the setting time, and also reduces water consumption, which leads to an increase in the strength of the Roman cement paste.

Abstract. The influence of mineral additive, i.e. ground granulated blast-furnace slag on artificial gypsum stone humidity strains has been studied. The slag content was varied in the range from 0 to 0.33 by weight based on the total amount of the mixture. The measurements were carried out on prism samples with dimensions of 160x40x40 mm. The samples were placed vertically in containers with water, the deformations were measured using dial indicators. It was established that the humidity strain value depends on the content of the granulated milled blast-furnace slag. A maximum strain of over 0.001 m/m is observed for the gypsum stone without mineral additive. A relative strain is decreased with an increase in the slag content. Minimum humidity strain of 0.0003-0.0004 m/m was observed for the artificial gypsum stone with the relative slag content of 0.05-0.1 and more than 0.27. This fact confirms our assumption that the water concentrated in the contacts between the individual crystals and particles of the structure of gypsum stone has a wedging effect that contributes to a low water resistance of gypsum. The values of the humidity strains of the artificial gypsum stone are suggested for the use as additional indicators of its water resistance.

1 Introduction

Gypsum binder-based materials are characterized by the ecological safety, sufficient strength and durability and also by a low weight and relatively low heat and sound conductivity. Due to these advantages, gypsum materials are widely used for construction purposes. However, their insufficient water resistance that results in an essential loss of strength in the case of their water saturation and/or wetting restricts the fields of their broad application. A low water resistance of gypsum materials is mainly explained by the calcium dihydrate solubility and the wedging forces that are created by the water that penetrates into the pores.

As of today, many methods are available that can increase the gypsum water resistance, in particular a decrease in the water-to-gypsum ratio, an addition of polymer additives, impregnation and hydrophobization of the surfaces of gypsum stone, combination with hydraulic binders, addition of active mineral additives and additives-microfillers that contribute to the formation of the dense structure of gypsum stone. During the studies carried out to improve the compositions of gypsum binder the water resistance was evaluated by the softening factor, i.e. the compression strength ratio in the water saturated state and initial dry state.

Nevertheless, the contribution made to the water resistance of gypsum stone by abovementioned wedging forces that are created by the water that penetrates into the pores requires additional studies. However, it is known to us that these forces simultaneously result in the humidity strains of the artificial stone. Hence, the studies of the volumetric strains of the artificial gypsum stone with mineral additives and their relations with the water resistance are an important task.

2 Analytical review of literature sources

A low water resistance of gypsum items is explained by a rather high solubility of gypsum dihydrate equal to 2.04 g/l [1]. In addition, the water that penetrates into inter-crystalline cavities is adsorbed by hard surfaces and the wedging pressure is created between them that disrupts local contacts between the crystals. An assumption can be made that these reasons are interrelating and enhance each other.

Gypsum modifications are described in many research papers [2-6], etc. The water resistance of gypsum binders can be increased by a decrease in the water-to-gypsum ratio, by combination with hydraulic binders [4-6] and by addition of mineral additives-fillers [7-12], hydrophobization additives [12], polymers and the fiber [13]. The authors give different explanations to the reasons that contribute to the improvement of the properties. The complex mineral additive that includes the granulated milled blast-furnace slag, fly ash and pazzolana (zeolite) provides the densification of the structure of the cement stone and an increase in its strength, according to [15]. In [16], the internal strain of the artificial stone can be controlled through the addition of the slag-lime binder to the Portland-cement clinker. To improve physical and mechanical characteristics, the authors [17] modify binding substances by clay fillers. The electrolytes, especially in the form of the complex additive, provide an increase in the water impermeability

* Corresponding author: aaplugin@gmail.com

[18] and strength [19] of cement composites. In [19], such an influence of potassium and sodium sulfates and carbonates is explained by the modification of the microstructure and porous structure.

The structure and the properties of gypsum materials can also be controlled through the addition of mineral fillers and other binders of a different composition and dispersion degree [4-13; 20-22]. The most stable compositions of gypsum binders are gypsum-cement-pazzolana binders [1]. Among their hydration products are not only calcium dihydrate sulfate crystals but also low-basic calcium hydrosilicates and other slightly soluble hydrates. According to [14], these can form electroheterogeneous contacts with calcium dihydrate sulfate crystals that provide the formation of the water-resistant structure.

In [4], the water resistance of gypsum made of waste is attained by mixing it with the fly ash and Portland cement. The authors [21] add mineral and organic modifiers to gypsum and explain their action by the enhancement at the atomic and molecular level. In [20], the industrial waste that contains calcium dihydrate sulfate is used as a substituent of natural gypsum. In order to form a denser structure of gypsum stone, the authors [22] use the methods of the computer simulation of the composition of the raw mixture and in [2] they substantiate an optimal proportion that provides a maximum strength for the mixed binder made of slag, gypsum and clinker. In [5, 7, 10, 13], consideration is given to the microreinforcing action of mineral additives on gypsum stone and its effect on the strength. An addition of 14% of the ultra-dispersed zeolite to gypsum resulted in an increase of its water resistance from 0.31 to 0.84 [7]. An analogous effect [10] caused by the addition of zeolite and carboxylate is also explained by an essential change in the structure. In [13], an increase in the gypsum strength is explained by the effect of the dispersed reinforcement.

The effect of mineral and chemical additives on the gypsum water resistance was studied in [4; 7; 8; 11; 12]. The authors [8] modify gypsum by the metallurgy dust and multi-walled carbon nanotubes. They explain an observed increase in the water resistance by the formation of amorphous hydrosilicate structures on the gypsum crystal surface that bind gypsum crystals and prevent an access of water to them. In [9], gypsum is modified by the ultradispersed metallurgy dust and anhydride. The authors note a change in the morphology that results in the densification and an increased strength and water resistance. In [11], the authors state an intensification of the hydration and the formation of a denser structure due to the addition of the complex chemical additive. Micro- and nanoadditives of silicon carbide *SiC* that act as crystallization centers and result in the formation of larger crystals also intensify hydration and structure formation processes [12].

It is known [18] that the properties of the materials that are based on inorganic binders are conditioned by the availability of the electrostatic interaction of the double electric layers of structural elements. The strength and the water resistance of hydraulic binders are defined by strong electroheterogeneous contacts between the particles with opposite surface charges. Air-setting binders consist of the elements that have similar charges, therefore their strength and water resistance are defined by electrohomogeneous contacts with the intermolecular interaction. In [3], a hypothesis was put forward and it was proved that maximum possible physical and mechanical parameters of the cured_mineral binders can be attained due to the equality between themselves of the total areas of particle surfaces of a dispersed phase in the volume unit that have opposite surface charges. We believe that such equality can be attained through the composition control of the hydration products of the binder and the embedment of highly-dispersed inert particles into their structure. The gypsum stone strength is mainly defined by electrohomogeneous contacts between the gypsum crystallohydrates with a weak intermolecular interaction. These contacts are destroyed even by insignificant strains [3; 14]. To provide an appropriate water resistance and to increase the strength of gypsum binders the research papers [2; 14] suggest to add mineral additives to their composition that act as the fillers and microfillers with defined surface charges and it will result in the formation of an ample amount of electroheterogeneous contacts with the edges of gypsum crystallohydrates.

It was shown in [18] that the water resistance of gypsum with mineral additives, in particular ground granulated blast-furnace slag depends on the thickness of the interlayers of gypsum dihydrade between the particles of mineral fillers. The thickness of these interlayers is related to the structural characteristic of the filled gypsum stone, i.e. the separation factor of the particles of mineral filler by gypsum dehydrate η. The dependence of the strength of artificial stone and especially its water resistance [3] has a wavelike or extreme character with the peaks that correspond to the optimal values of separation coefficient η_{opt}. A maximum strength and water resistance are provided in the case of the formation of a denser packing of the gypsum dihydrate crystals in the interlayers between the particles of the mineral filler and in the case of the correspondence of an actual value of the separation coefficient η to its optimal value η_{opt}. For this purpose, it was suggested in [3] to provide an optimal value of the separation coefficient η_{opt} that is analogous to the optimal separation coefficients of the grains of coarse filler η_{opt} and the fine filler η_{opt} in the concretes. The density of gypsum stone can also be increased through the use of nanodispersed fillers that fill intercrystalline cavities by embedding into the structure and contribute thus to the structure densification [3; 14]. In this case, the number and the dispersion degree of the fillers are selected to provide the formation of the dense packing of matrix particles in the interlayers between the structure forming parts, in particular gypsum crystallohydrates are supposed to be formed between the slag particles and nanodispersed particles should be formed between gypsum crystallohydrates [3; 14]. In addition, the nanodispersed particles of the filler can act as crystallization centers increasing thus the dispersion of crystallohydrates and making the structure denser.

Based on the conceptions of the contribution made to a low water resistance by the wedging effect of the water concentrated in the contacts between the individual crystals and particles in its structure it was suggested to use a relative linear humidity strain caused by the water saturation (swelling) ε_w in m/m as an additional indicator of water resistance.

3 Research methods and materials

To carry out experimental investigations we used the gypsum building plaster G-10, ground granulated blast-furnace slag "Zaporizhstal" and the plasticizing additive, i.e. sodium lingosulphonate in the amount of 2% of the gypsum mass.

The ground granulated blast-furnace slag "Zaporizhstal" had the following parameters: chemical composition, %: SiO_2 – 36.5; Fe_2O_3 – 5.1; Al_2O_3 – 6.7; CaO – 46.5; MgO – 5.9; SO_3 – 4.2; the basicity module – 1.19; the true density – 2810 kg/m^3; the specific surface – 3000 cm^2/g; the granulometric composition was defined using the MBI-6 microscope ruler, %: up to 10 μm -2.5; for the range of 10 to 23 μm – 11; 2 to 36 μm – 8.6; 36 to 49 μm – 12.9; 49 to 62 μm – 8.8; 62 to 75 μm – 6.8; 75 to 88 μm – 9.2; 88 to 101 μm – 6.7; 101 to114 μm – 10.6; 114 to 127 μm – 10.3; above 127 μm – 12.7. Hence, about 80 % fall to the range of 10 to130 μm, and the average particle size is 60 μm.

The humidity strain was defined using prism-like specimens with the size of 160×40×40 mm that were cured for at least 7 days and nights and dried in the temperature range of 18 to 22°C and the relative humidity of 40 to 60% to get the constant weight. At least three specimens were used to test each composition. The specimen length L was measured in advance. Each specimen was inserted vertically into the container and the steel or glass plate was laid over it. The indicator of a clock type that was clamped in the laboratory holder (Fig.1) was connected to it and initial indicator readings were recorded.

The container was filled with water to the level of the upper edge of the specimen and the indicator readings were taken every 0.25 to 0.5 hours during first 6 hours. A sight was taken on it for at least 24 hours.

The values of absolute linear humidity strain were measured for each time point i according to the indicator readings X_i:

$$\Delta L_i = X_i - X_0, \text{ mm}, \tag{1}$$

where X_0 is the initial indicator reading prior to pouring a required amount of water.

A relative humidity strain was measured for each time point:

$$\varepsilon_w = \Delta L_i / L \tag{2}$$

Based on ε_w values, the kinetic curve of the dependence of ε_w on time was constructed and using this curve a maximum value of ε_w was defined and the time required to attain it was recorded.

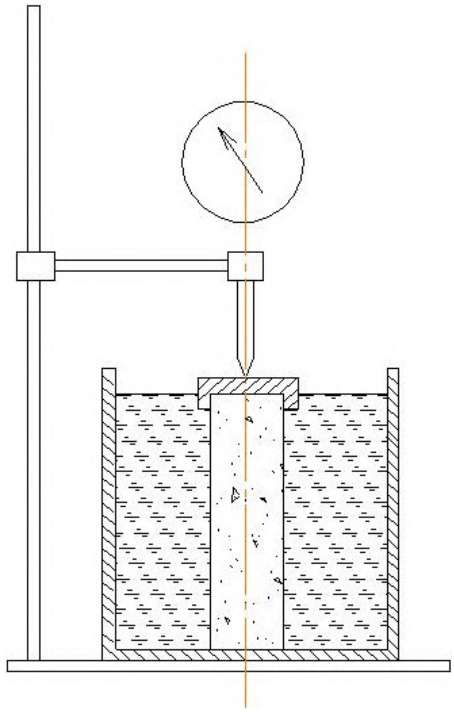

Fig. 1. Measurements of the humidity strains of artificial gypsum stone with mineral additives.

4 Research data and their discussion

The research data are given in Fig. 2 and 3 and in Table 1.

Table 1. Maximum humidity strains ε of the artificial gypsum stone with a different relative content of the mineral additive in the form of ground granulated blast-furnace slag S (G+S)

No	S/ (G+S)	W/ (G+S)	A relative humidity strain of the specimens ε_w, m/m.						ε_{wmid}, m/m
K	0	0.35	0.64020	0.78047	1.60285	1.05040	0.91300	1.12973	1.01937
1	0.09	0.32	0.59156	0.43218	0.27623				0.43332
2	0.17	0.29	0.54071	0.39653	0.54162	0.96342	0.91690	0.78600	0.69081
3	0.23	0.27	1.12251	0.72981	0.67662				0.84298
4	0.29	0.25	0.75382	0.38879	0.29888				0.48050
5	0.33	0.23	0.35869	0.32983	0.76449				0.34426

Fig.2 and 3 and Table 1 show that as soon as the specimens are immersed into the water their length starts to elongate immediately due to the humidity strain, i.e. the swelling. The strain was developed during 3 to 5

https://doi.org/10.1051/e3sconf/202128007003

hours and after that it attained a maximum value and actually immediately it began to come down.

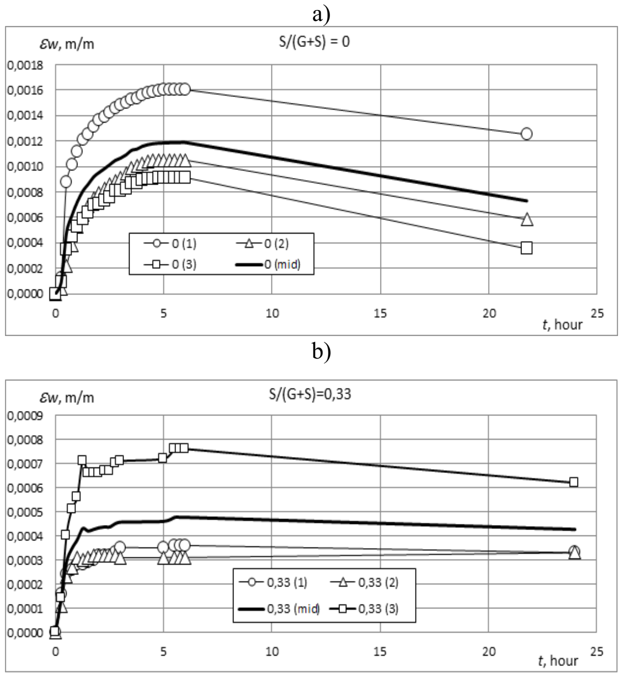

Fig.2. The dependence of the humidity strain ε_w on time t for the artificial gypsum stone with a relative content of the mineral additive, in particular ground granulated blast-furnace slag S/(G+S): a – 0 (gypsum stone without additives); b – 0.33.

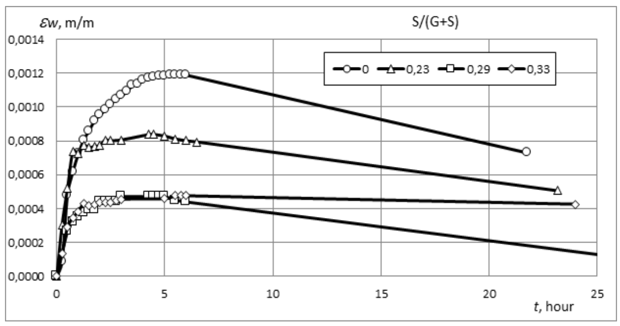

Fig.3. The dependence of the humidity strain ε_w on time *t* for the artificial gypsum stone with a different relative content of the mineral additive, in particular ground granulated blast-furnace slag S/(G+S).

It can be seen from Fig. 3 and 4 and Table 1 that the value of humidity strain depends on the content of the mineral additive, i.e. granulated milled blast-furnace slag. A maximum strain is observed for the gypsum stone without mineral additive. A relative strain is decreased with an increase in the slag content. However, this decrease has no linear character; it is wavelike by analogy to the dependences of the strength and water resistance on the slag content.

It can be seen from Fig.3 and 4 and Table 1 that minimum humidity strains are observed for artificial gypsum stone with a relative slag content of S/(G+S) 0.05–0.1 and above 0.27. It agrees with the character of the dependences constructed for the water resistance of the artificial gypsum stone as a function of relative slag content (Fig. 5) and it confirms our assumption that the wedging effect of water concentrated in the contacts between the individual crystals and particles in its structure contributes to a low water resistance of gypsum. Hence, it is reasonable to use the values of humidity strains of artificial gypsum stone as additional indicators of its water resistance.

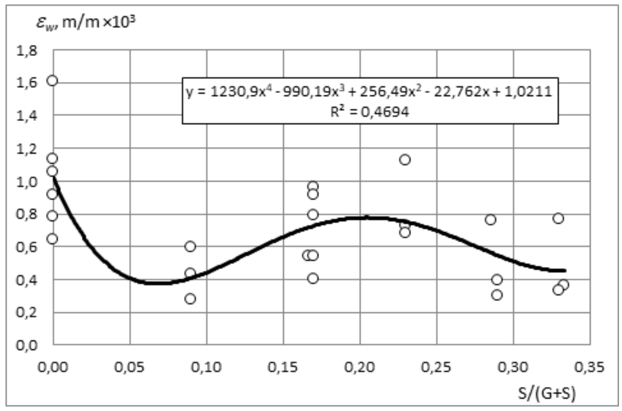

Fig.4. Dependence of a maximum humidity strain ε of the artificial gypsum stone on a relative content of the mineral additive, in particular ground granulated blast-furnace slag S/(G+S).

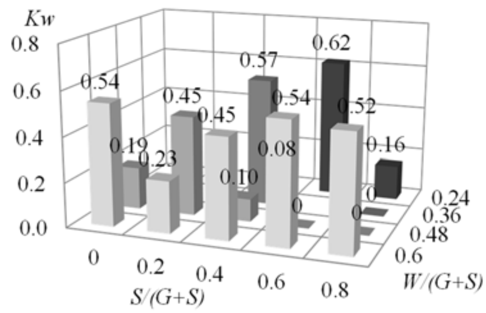

Fig. 5. The dependence of the strength and water resistance ratio K_w of gypsum-slag stone at the age of 7 days on the content of the filler –slag S/(G+S) and water-solid ratio W/(G+S) [14].

Therefore, the supplemental addition of the ground granulated blast-furnace slag to gypsum with the mineral additive results in no increase in the strength of artificial gypsum stone and it can even condition a certain reduction of it. However, its strength is increased in the water saturated state and it results in an essential increase in the water resistance, the softening factor in increased in the range of 0.6 to 0.8 and it can attain 1.

The information given above confirms the theoretical conception that the addition of mineral additives to gypsum results in an increased amount of electroheterogeneous contacts in the artificial stone structure due to the fact that the pores are filled by additive particles.

5 Conclusions and recommendations

The experimental investigations show that as soon as the specimens are immersed into the water their length starts to elongate due to the humidity strain, in particular, the swelling. The strain was developed during 3 to 5 hours and after that it attained a maximum value and actually immediately it began to come down.

It was established that the value of humidity strain depends on the content of the mineral additive, i.e. granulated milled blast-furnace slag. A maximum strain is observed for the gypsum stone without mineral additive. A relative strain is decreased with an increase in the slag content. However, this decrease has no linear character; it is wavelike by analogy to the dependences of the strength and water resistance on the slag content. Minimum humidity strains are observed for the artificial gypsum stone with a relative slag content of S/(G+S) 0.05–0.1 and above 0.27.

It confirms our assumption that the wedging effect of water concentrated in the contacts between the individual crystals and the particles in its structure promotes a low water resistance of gypsum. Hence, it is reasonable to use the values of humidity strains of artificial gypsum stone as additional indicators of its water resistance.

Abstract. Concretes mixed with seawater are characterised by enhanced performances, but action of chlorides and sulfates ensures the risk of reinforcement corrosion. Application of high consistency fresh concretes ensures changes in hardened concrete structure that causes the problem of steel reinforcement passive state ensuring. Thus mixing of plasticized concretes by seawater actualizes the search for means of steel corrosion prevention. Alkali-activated slag cements (further, AASC's) reduce effect of ions Cl^- and SO_4^{2-} on steel reinforcement in concrete due to their exchange for ions OH^- in the structure of zeolite-like alkaline hydroaluminosilicates. Complex additive «portland cement - calcium aluminate cement - clinoptilolite» was proposed to enhance the protective properties of AASC concretes to steel reinforcement. The results of DTA, X-ray diffraction, electron microscopy, microprobe analysis show that complex additive ensures to prevent steel reinforcement corrosion in AASC concrete mixed with seawater due to binding Cl^- and SO_4^{2-} ions in Kuzel's salt in AASC hydration products and exchange of these aggressive ions with OH^- ions in the structure of clinoptilolite. This effect of complex additive confirmed by surface state and the absence of mass loss of steel rebars embedded in plasticized AASC fine concrete mixed with seawater after 90 d of hardening.

1 Introduction

The actuality of green materials implementation is due to their conformity with modern tendencies in construction engineering concerning efficient consumption of raw materials and energy resources [1], as well as responsible attitude to ecology of the environment [2]. Cements, which contain inorganic additives, fully comply modern tendencies for sustainable development of mankind [3]. The ecological benefits of such cements are caused by reduction of CO_2 emission due to substitution of portland cement clinker by inorganic additives [4]. At that, materials based on the mentioned cements are characterized by high quality, functionality and durability. Efficiency of high early strength multicomponent cements based on ground blast furnace slags (further, GBFS), zeolite and fly-ash in mortars was shown [5]. Additives of polydisperse zeolite tuff and perlite provide positive effect on concrete strength in different conditions [6]. Addition of zeolite or highly dispersed chalk enhances strength of cements [7], as well as crack resistance [8] and freeze-thaw resistance of concretes [9]. Portland cements containing GBFS are characterized by increased corrosion resistance and can be used in protective materials [10].

Alkali-activated slag cement (further, AASC) can be consider as the most perspective environmentally friendly ones. Alkali activation of aluminosilicate raw materials is widely used [11, 12]. The ecological benefits of AASC's are caused by reduction of CO_2 emission while consumption of by-products as well as waste products [13]. AASC mortars and concretes are characterized by increased strength [14], heat resistance [15, 16], corrosion resistance [17], freeze-thaw resistance [18], waterproof [19] and fire resistance [20, 21] in comparison with analogues based on traditional clinker cements. Beside of high performances, AASC's can be used in decorative materials [22]. Radioactive wastes [23] and manufacturing waters [24] are effectively used in safety building materials based on AASC.

As perspective direction being taken to improve the environmental friendliness of modern concretes, has been using of seawater. It's known, that the consumption of water in concrete is 9 % of the total consumption of industrial water [25]. Thus, the most recent substantial interest has been placed on seawater as an alternative solution for impeding the exploitation of freshwater.

Seawater can be used as an activator of GBFS's hydraulic properties [26, 27, 28]. This phenomena is caused by salts of strong acids (further, SSA's), like chlorides and sulfates, dissolved in seawater [29, 30]. At that, seawater ensures increasing of AASC concrete consistency [31] and concrete strength [32] that is explained by effect of SSA's [33, 34].

However, corrosion of steel reinforcement under action of chlorides and sulfates is the main problem for concretes mixed with seawater. There are two main processes during corrosion action on steel reinforcement: carbonation and pitting corrosion, caused by chlorine-ions [35]. Sulfate-ions don't cause immediate depassivation of steel reinforcement, but determine formation of hydrogen

* Corresponding author: alexandrkp@gmail.com

sulfide (H_2S), which catalyze oxidation (carbonation) of hydrate phases.

The stability of passive film on the surface of steel reinforcement in AASC concrete, mixed with seawater, depends on concentration of free chlorine-ions and OH^- ions in pore solution, primarily in contact zone between reinforcement and concrete [36]. The passive state of steel reinforcement is provided at molar ratio of $Cl^-/OH^- \leq 0.6$ in pore solution [37].

The modern requirements to high consistency fresh concretes are governed by practice. This way the disturbance of reinforcement passive state can be caused by changes in hardened concrete structure [38]. Problem with ensuring of steel reinforcement passive state in AASC concretes, mixed with seawater, is intensified. Thus, the means for protection of steel reinforcement in plasticized AASC concretes must be developed.

It was shown, that the modification by complex additive (further, CAD) based on SSA's ensures decreasing of AASC concrete drying shrinkage as well as enhancement of crack resistance [39]. This type of modification provides mitigation of steel reinforcement corrosion. Effect of CAD is caused by less water, acceleration of crystallization, alteration of porous structure as well as by changes in morphology of hydrated phases [33, 34].

One of the ways to prevent the steel reinforcement corrosion in AASC concrete mixed with seawater is decreasing of chlorine ions in pore solution due to their binding in low soluble compounds. It's well-known that hydration products of AASC are able to bind chlorine-ions. Alkaline hydroaluminosilicates, as analogues of natural zeolites, can be refered as such phases [29]. Apart from alkaline hydroaluminosilicates, free chlorine can be binded in Cl-bearing phases like hydrotalcite $[Mg_3Al(OH)_8]Cl\cdot3H_2O$ and hydrocalumite $3CaO\cdot Al_2O_3\cdot CaCl_2\cdot10H_2O$ [40]. These phases are suitable for chlorine binding both due to exchange processes and physical adsorption [41, 42, 43]. It was shown the binding of chlorine-ions by hydrosilicate C–S–H and hydroaluminosilicate C–A–S–H gel phases [44, 45].

Formation of phases, which provide binding of Cl^- and SO_4^{2-} ions, was proposed to prevent steel reinforcement corrosion in AASC concrete. It's well-known that chlorine can be binded by tricalcium aluminate ($3CaO\cdot Al_2O_3$) in AFm phases (Al_2O_3-Fe_2O_3-mono), which are characterized by greater stability comparing to AFt phases (ettringite) while increasing alkalinity of hydration medium [46, 47, 48]. The AFm phases can include different anions (Cl^-, SO_4^{2-}, CO_3^{2-}, OH^- etc.). Thus, AFm phases can be presented by monocarboaluminate, hemicarboaluminate, stratlingite, hydroxyl-AFm and monosulfoaluminate [49]. It was shown formation of nitrate containing AFm phase along with chloride and sulfate containing ones [50].

The above results cause reasonable application of calcium aluminate cement and portland cement as additives in AASC to ensure formation of highly-calcium hydroaluminates $3CaO\cdot Al_2O_3\cdot10H_2O$ for prevention of steel reinforcement corrosion due to binding of Cl^- and SO_4^{2-} ions. Highly-calcium hydroaluminates $3CaO\cdot Al_2O_3\cdot10H_2O$ can be formed due to interaction of portlandite $Ca(OH)_2$ (hydration product of portland cement) with low-calcium hydrosilicates (hydration product of calcium aluminate cement) [51]:

$$CaO\cdot Al_2O_3\cdot(6\ldots8)H_2O + 2Ca(OH)_2 \rightarrow$$
$$\rightarrow 3CaO\cdot Al_2O_3\cdot10H_2O \quad (1)$$

$3CaO\cdot Al_2O_3\cdot10H_2O$ ensures binding Cl^- and SO_4^{2-} ions in low soluble AFm phases [52]:

$$3CaO\cdot Al_2O_3\cdot10H_2O + Cl^-, SO_4^{2-} + H_2O \rightarrow$$
$$\rightarrow 3CaO\cdot Al_2O_3\cdot CaCl_2(SO_4)\cdot10H_2O \quad (2)$$

Application of aluminosilicate ionites such as clinoptilolite (natural zeolite) in AASC concrete composition, mixed with seawater, can be mean for prevention of steel reinforcement corrosion. Zeolites are known, first of all, as cationites which exchange Na^+ ions with Ca^{2+} ions, but can also act like anionites to exchange OH^- ions with Cl^- and SO_4^{2-} ions [53]. Clinoptilolite supplements anionite function of alkaline hydroaluminosilicates (analogues of natural zeolites) during AASC hydration.

The above results allow predicting prevention of steel reinforcement corrosion in plasticized AASC concrete mixed with seawater due to application of CAD «portland cement - calcium aluminate cement - clinoptilolite».

The aim of this research was to investigate the effect of seawater on the performances of plasticized AASC concrete and to ensure prevention of steel reinforcement corrosion due to application of CAD «portland cement - calcium aluminate cement - clinoptilolite».

2 Raw materials and methods

GBFS (CaO – 47.30 %; SiO2 – 39.00 %; Al_2O_3 – 5.90 %; Fe_2O_3 – 0.30 %; MgO – 5.82 %; SO_3 – 1.50 %; TiO_2 – 0.31 %), basicity modulus= 1.11, content of glass phase= 84.0 %, specific surface= 450 m^2/kg (by Blaine), was used as an aluminosilicate component of AASC.

Alkaline components of AASC were presented by:

- soda ash (Na_2CO_3), dry state;
- five-water sodium metasilicate ($Na_2SiO_3\cdot5H_2O$), dry state;

Two reference compositions of AASC were used:

- based on soda ash (GBFS – 93.50 %, soda ash – 6.50 % (3.80 % by Na_2O));
- based on sodium metasilicate (GBFS – 88.50 %, sodium metasilicate – 11.50 % (3.36 % by Na_2O));

The AASC's were also modified by CAD, which components were presented by:

- portland cement CEM I 42,5 R (PJSC Ivano-Frankivskcement, Ukraine);
- calcium aluminate cement ISTRA 40 (HeidelbergCement, Germany);
- natural zeolite (clinoptilolite) powder (by mass, %: SiO_2 – 72.5, Al_2O_3 – 13.1, Fe_2O_3 – 0.9, TiO_2 – 0.2, CaO – 2.1, MgO – 1.07, P_2O_5 – 0.003, K_2O+Na_2O – 5.03), fr. 0 - 0.1 mm, content of clinoptilolite ≤ 93.0 %, porosity 54.0 % (JSC Zeolite-Bio, Ukraine).

Content of CAD was 10.00 % by mass of AASC. Contents of CAD components, %: (portland cement + calcium aluminate cement) – 5, clinoptilolite – 5.

The ratio between portland cement and calcium aluminate cement was 2.17:1.00 taking into account formation of $3CaO{\cdot}Al_2O_3{\cdot}10H_2O$ according to reaction (1).

Surfactants were presented by:

- sodium lignosulphonate (further, LST) according to CAS 8061-51-6 (pH ≥ 8.5);

- sodium gluconate according to CAS 527-07-1.

AASC's were mixed with fresh water or with seawater, which was presented by aqueous solution of salts, % by mass of mixture: NaCl – 78.70, $MgCl_2$ – 9.80, $MgSO_4$ – 5.76, $CaSO_4$ – 3.75, KCl – 1.73, $CaCO_3$ – 0.29. Total concentration of seawater salts was 35 g/l.

The standard quartz sand according to EN 196-1 was used in AASC fine aggregate concretes (ratio AASC to sand = 1:3).

Reinforcement was presented by steel rebars, length 120 mm and diameter 4.1 - 4.3 mm.

Fresh concretes were prepared in mixer «Raimondi Iperbet» (Italy).

Consistency (workability) was determined by cone slump according to the national standard of Ukraine DSTU B V.2.7-114:2002.

Consistency class of fresh concrete was S4 (slump 160 - 210 mm).

The performances plasticized of AASC concretes (AASC:sand = 1:3) were determined on specimens 40x40x160 mm.

The state of embedded steel rebars in plasticized AASC concrete, mixed with seawater, was estimated according to following method. The basic rebars, length (120±2) mm and diameter from 3 to 6 mm, were embedded in specimens 40x40x160 mm of AASC concrete. These rebars were degreased by acetone and weighted with accuracy of ±0,001 g before embedding. After hardening of specimens in normal conditions (t=20±2 °C, *R.H.*=95±5 %) the basic rebars were reached from AASC concrete and etched during (25±5) min in 10 % solution of hydrochloric acid with adding of urotropine (1 % by acid mass) to remove rests of cement stone and products of corrosion. The reference rebars, which weren't embedded in concrete, were weighted and etched simultaneously with basic rebars. After etching the basic and reference rebars were cleaned by distilled water and were immersed in fat solution of sodium nitrate for 5 min. Then the rebars were wiped by filter paper, dried up and weighted. The mass loss of rebars were calculated as a ratio of mean differences between masses before and after etching to surface area.

Monitoring the structure formation was carried out by X-ray diffraction (XRD), differential-thermal analysis (DTA) and electronic microscope with microanalyzer

3 Results and discussion

Effect of CAD «portland cement - calcium aluminate cement - clinoptilolite» on structure formation of AASC, mixed with seawater, was investigated.

3.1 Structure formation of alkali-activated slag cement based on soda ash and mixed with seawater

XRD indicates the slightly crystallized low-calcium hydrosilicates such as CSH(B) (d= 0.307; 0.280; 0.183 nm) and gyrolite $2CaO{\cdot}3SiO_2{\cdot}2H_2O$ (d= 0.33; 0.268; 0.180 nm) after 90 d of hydration (Fig.1, curve 1). Besides, calcite (d= 0.307; 0.191; 0.160; 0.152 nm) is formed. Specified phases are typical for AASC [54].

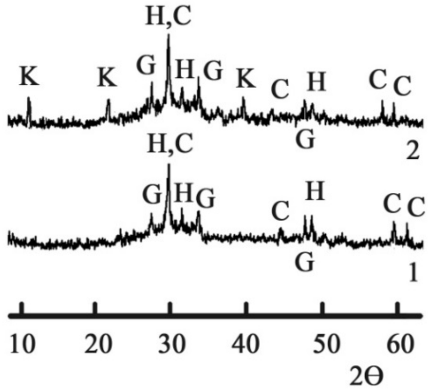

Fig. 1. XRD of alkali-activated slag cement mixed with seawater and hydrated during 90 d: 1 – the reference; 2 - modified by complex additive. Legend: H – calcium hydrosilicates CSH(B), G – gyrolite, C – calcite, K – Kuzel`s salt.

Clorine- and sulfate-binding zeolite-like minerals, which are similar to nosean $Na_8(Al_6Si_6O_{24})(SO_4){\cdot}H_2O$, sodalite $Na_4(Si_3Al_3)O_{12}Cl$, cancrinite $(Na,Ca)_8(Al_6Si_6O_{24})(CO_3,SO_4)_2{\cdot}2H_2O$ etc., can be predicted [29, 55]. However these hydrates were not identified because of their submicrocristalline state.

DTA confirms formation of slightly crystallized calcium hydrosilicates CSH(B) by endothermic effect at t= 175 (dehydration) and exothermic effect at t= 865 °C (recrystallization into wollastonite). The endothermic effects at t= 175 and 700 °C (stepped dehydration) and exothermic effect at t= 865 °C (recrystallization into wollastonite) are typical for gyrolite $2CaO{\cdot}3SiO_2{\cdot}2H_2O$ (Fig. 2, curve 1). The endothermic effect at t= 890 °C confirms presence of $CaCO_3$ (Fig. 2, curve 1).

According to electron microscopy (Fig.3 a), gel-like low-calcium hydrosilicates CSH(B) (content in probe, %: CaO – 30.19, SiO_2 - 35.42) (Fig.3 b) and prismatic formations of calcite $CaCO_3$ (content in probe, %: CaO - 53.78, CO_2 - 41.29) (Fig.3 c) were identified in the reference AASC.

Chlorine and sulfate containing AFm phases, known as Kuzel's salt $3CaO{\cdot}Al_2O_3{\cdot}0,5CaCl_2{\cdot}0,5SO_4{\cdot}10H_2O$ (d= 0.83; 0.42; 0.23 nm) [56], were also identified in hydration products of AASC, modified by CAD and mixed with seawater (Fig.1, curve 2). Specified phases were formed due to binding Cl^- and SO_4^{2-} ions by calcium hydroaluminate $3CaO{\cdot}Al_2O_3{\cdot}10H_2O$ according to reaction (2).

The presence of Kuzel's salt in hydration products of AASC, modified by CAD and mixed with seawater, was confirmed by endothermic effects at t= 330 °C (dehydration) and 480 °C (departure of chloride) as well

 https://doi.org/10.1051/e3sconf/202128007004

as by exothermic effect at t= 1000 °C (decomposition of sulfate) (Fig. 2, curve 2). Relocation of effects to higher temperatures ensures formation of CSH(B) and gyrolite with advanced crystallization.

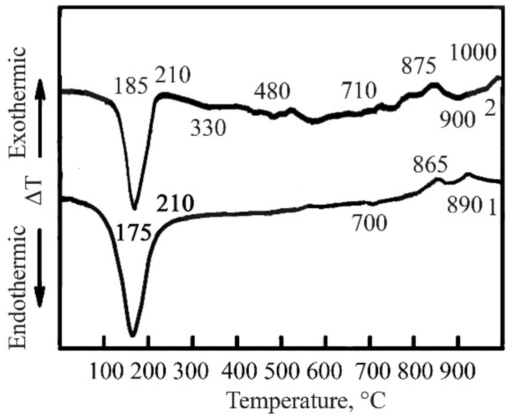

Fig. 2. DTA of alkali-activated slag cement mixed with seawater and hydrated during 90 d: 1 – the reference; 2 - modified by complex additive.

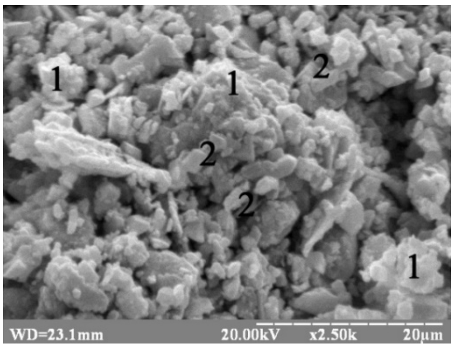
a)



b)

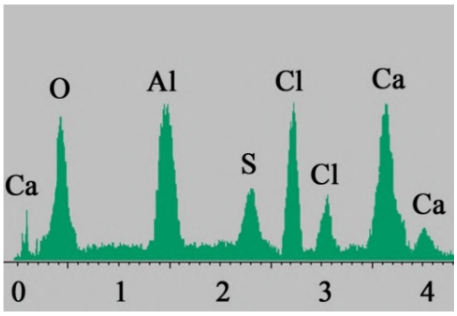

Fig. 4. Microstructure of the reference alkali-activated slag cement mixed with seawater and hydrated during 90 d: a – SEM images; b – microprobe analysis in points 1.

The modification of AASC by CAD causes formation of low-calcium hydrosilicates with a higher level of crystallization as well as hexagonal thin plates of Kuzel's salt (Fig. 4 a). The content of oxides confirms formation of Kuzel's salt, %: CaO – 32,72, Al_2O_3 – 21,51, Cl – 10,27, SO_3 – 9,56) (Fig.4 b).

3.2 Structure formation of alkali-activated slag cement based on sodium metasilicate and mixed with seawater

XRD ensures formation of slightly crystallized low-calcium hydrosilicates such as CSH(B) and gyrolite (Fig.5, curve 1). The presence of zeolite-like minerals (similar to nosean, sodalite, concrinite etc. by composition), which can bind Cl^- and SO_4^{2-} ions, can be assumed.

The presence of mentioned hydrosilicates was confirmed (Fig. 6, curve 1). Gel-like low-calcium hydrosilicates CSH(B) (Fig.7 a) (content in probe, %: CaO – 32.35 SiO_2 – 34.71) can be identified in the reference AASC after 90 d of hydration (Fig.7 b).

According to XRD, low-calcium hydrosilicates and Kuzel's salt were fixed as hydration products of AASC modified by CAD (Fig.5, curve 2).

These hydrates can be confirmed by DTA (Fig. 6, curve 2). Displacement of mentioned effects to higher temperatures ensures formation of CSH(B) and gyrolite with advanced crystallization.

The phase composition of modified AASC (Fig.8 a) is represented by low-calcium hydrosilicates as well as by hexagonal thin plates of Kuzel's salt (content in probe, %:

 https://doi.org/10.1051/e3sconf/202128007004

CaO – 31.22, Al_2O_3 – 24.87, Cl – 12.43, SO_3 – 10.94) (Fig.8 b).

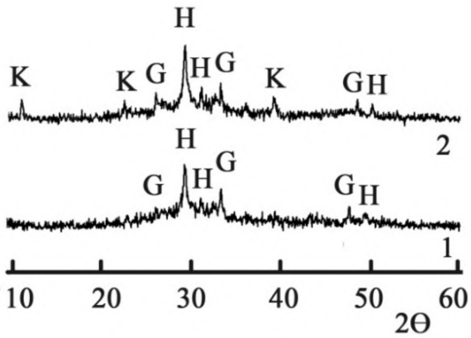

Fig. 5. XRD of 90 d hydrated alkali-activated slag cement mixed with seawater: 1 – the reference; 2 - modified by complex additive. Legend: H – calcium hydrosilicates CSH(B), G – gyrolite, К – Kuzel`s salt.

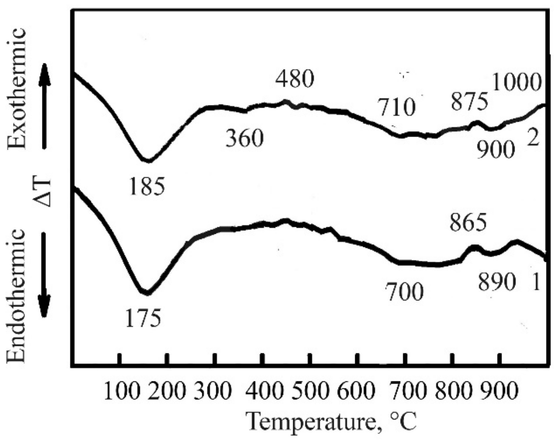

Fig. 6. DTA results of 90 d hydrated alkali-activated slag cement mixed with seawater: 1 - the reference; 2 - modified by complex additive.

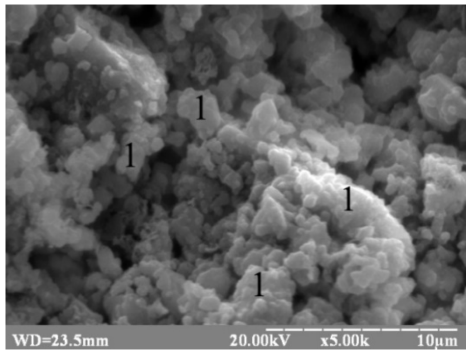
Hence, CAD «portland cement - calcium aluminate cement - clinoptilolite» ensures binding of Cl- and SO_4^{2-} ions in structure of hydrated AASC based on soda ash or sodium metasilicate while mixing by seawater. Interaction between hydration products of portland cement and calcium aluminate cement provides formation of high-calcium hydroaluminates like $3CaO{\cdot}Al_2O_3{\cdot}10H_2O$, which bind the mentioned ions in Kuzel's salt. Clinoptilolite, as component of CAD, supplements action of alkaline hydroaluminosilicates (typical hydration products of AASC) with replacement of OH- ions to Cl- and SO_4^{2-} ions.

Specified structure formation of AASC, mixed with seawater, ensures prevention of steel reinforcement corrosion due to minimization of free Cl^- and SO_4^{2-} ions in pore solution of artificial stone.

3.3 Effectiveness of complex additive in alkali-activated slag cement plasticized fine concrete

The effect of CAD «portland cement - calcium aluminate cement - clinoptilolite» on protective properties of plasticized AASC fine concrete, mixed with seawater, to steel reinforcement was investigated. Mass loss of steel rebars, which were reached from plasticized AASC concrete after 90 d of hardening was fixed.

a)



b)

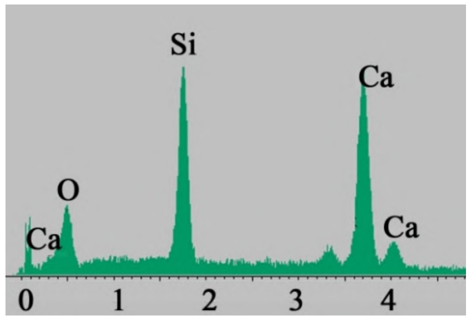


Fig. 7. Microstructure of the reference alkali-activated slag cement mixed with seawater and hydrated during 90 d: a – SEM images; b – microprobe analysis in points 1.

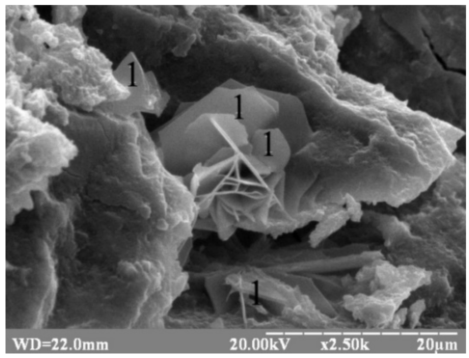
a)



b)

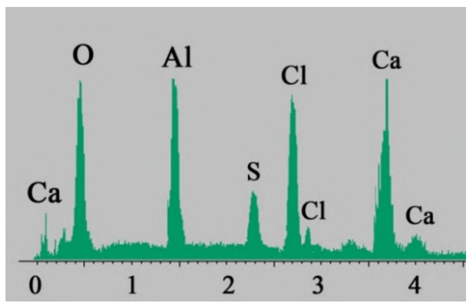


Fig. 8. Microstructure of 90 d hydrated alkali-activated slag cement, modified by CAD and mixed with seawater: a – SEM images; b – microprobe analysis in points 1.

AASC's, based on soda ash as well as on sodium metasilicate, were used as bases of fine concrete. AASC fine concrete was modificated by CAD «portland cement - calcium aluminate cement - clinoptilolite». The CAD composition, %: portland cement – 34.2, calcium aluminate cement – 15.8, clinoptilolite – 50.0. AASC fine concrete was plasticized by LST and sodium gluconate.

W/C ratios in AASC concrete based on soda ash and sodium metasilicate were 0.46 and 0.43 agreeably. W/C ratios in AASC concrete while mixing with seawater were 0.44 and 0.41 agreeably. This is evidence of AASC fresh concrete workability increasing while mixing with seawater [54]. At that, increasing of AASC concrete strength while mixing with seawater was fixed. Thus, compressive strength of AASC concrete based on soda ash while mixing with seawater corresponds to values of 35.7 MPa that is on 21.8 % greater comparing with one mixed with water (29.3 MPa). Compressive strength of AASC concrete, based on sodium metasilicate and mixed with seawater, is on 10.9 % greater comparing with one mixed with water (45.8 and 41.3 MPa agreeably). Enhancement of AASC fine concrete strength while mixing with seawater comparing with one mixed with water is caused by effect of SSA's [30, 33, 34].

The effect of CAD on protective properties of plasticized AASC concrete, mixed with seawater, to steel reinforcement was investigated.

Mass loss of steel rebars weren't fixed. This is evidence of no effect of Cl^- and SO_4^{2-} ions on steel reinforcement in plasticized AASC fine concretes, modifided by CAD and mixed with seawater.

The state of steel rebars before embedding (Fig. 9, 10) and embedded in specimens after 90 d of hardening (Fig. 11, 12) were compared.

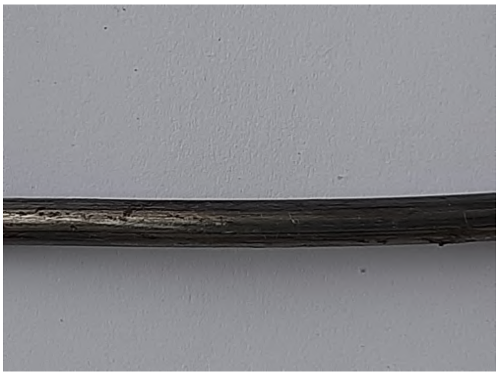

Fig. 9. Steel rebars before embedding in plasticized alkali-activated slag cement fine concrete (zoom x4) based on soda ash.

The absence of corrosion processes on surface of steel reinforcement in plasticized AASC concrete, mixed with seawater, was also confirmed by visual control.

Thus, effectiveness of CAD in plasticized AASC fine concrete for enhanced protective properties to steel reinforcement was confirmed.

Conclusion

1. Increasing of fresh concrete consistency as well as advanced strength of concrete based on alkali-activated slag cement while mixing with seawater was shown.

2. Prevention of steel reinforcement corrosion under the action of chlorides and sulfates in plasticized alkali-activated slag cement concrete mixed with seawater was ensured due to application of complex additive «portland cement - calcium aluminate cement - clinoptilolite».

3. Enhancement of protective properties of plasticized alkali-activated slag cement concrete, mixed with seawater, to steel reinforcement is explained by binding of ions Cl^- and SO_4^{2-} in Kuzel's salt (AFm phase) as well as by exchange of OH^- ions with these aggressive ions in structure of clinoptilolite.

Abstract. One of the essential tasks for a sustainable future is to reduce harmful emissions into the atmosphere significantly. Cement production is the world's largest industrial carbon pollutant, accounting for 8 % of global emissions. More than 2.2 gigatons of carbon dioxide are emitted into the atmosphere every year. Therefore, reducing the energy intensity of products and reducing the number of harmful emissions in cement production is becoming critical. One strategy to reduce cement production emissions is to reduce the most energy-consuming component in cement – clinker. In this case, various activation methods are used for maintaining the same level of cement activity. One of these methods is the impact on the hardening binder with magnetic fields. The paper presented a study of hydration processes of blast-furnace cement activated by a magnetized ferromagnetic additive. The work established that the introduction of pre-magnetized ferromagnetic dust into blast-furnace cement composition has an activating effect on binder hydration. It shows that activation occurs both in the initial and long periods of hardening. The nature of the mutual influence of the components of the hydration system alite-lime-slag in a modified binder was revealed. The investigation determined that the ferromagnetic additive, intensifying the process of slag hardening, increases the proportion of hydrated slag by 1.5-2 times. It was revealed that the formation of the ettringite framework in the modified binder's gel is completed within one day. It is shown that in the subsequent periods, hydration of aluminates occurs mainly due to the formation of tricalcium aluminate hexahydrate (C_3AH_6), which excludes destructive processes in the late periods of binder hardening. It has been established that under the action of a ferromagnetic additive, the degree of crystallization of hydro silicates in the modified binder increases.

1 The problem and its relationship with scientific and practical tasks

Cement is one of the essential building materials. More than 4 100 000 tons of cement are produced annually globally [1], and CO_2 emissions during its production are 6.5 % of the global emissions or more than 2.2 gigatons of carbon dioxide per year [2, 3]. In the foreseeable future, there are no prerequisites for reducing the need for cement. Therefore, reducing its products' energy intensity and reducing the number of harmful emissions is becoming increasingly important. One way to reduce cement production emissions is to introduce production waste into their composition, including granulated blast-furnace slags.

The introduction of slags makes it possible to combine a decrease in the proportion of clinker in cement with production waste disposal. However, the introduction of mineral additives, as a rule, leads to a decrease in cement activity [4]. Therefore, the proportion of active mineral additives in cement is limited. A further increase in active mineral additives' share-production waste is achieved through various cement activation methods. One of these methods is the impact on the hardening binder with magnetic fields.

2 Analysis of research and publications

In [5], it is noted that magnetic fields significantly affect the spin dynamics and control the spin multiplicity of radical pairs. The electron paramagnetic resonance method made it possible to determine that cement is a paramagnetic substance and that cement hardening occurs due to paramagnetic centers' recombination [5-10]. Thus, the possibility of the influence of magnetic fields on binders' hydration processes has been proved.

Traditional methods of exposure to magnetic fields on hardening cement are short-term and therefore do not lead to significant and stable results. It was proposed in works [11] to use finely dispersed magnetized ferromagnetic additives to activate blast-furnace cement. As such an additive in the research, we used fine dust – waste from the metallurgical industry. In [12], the influence of the

* Corresponding author: budfac@gmail.com

additive's magnetic and dispersed properties on the activation effect was studied. Obtained in [12], dependences of cement strength on magnetization and particle dispersity and the additive small proportion (up to 2%) led to the conclusion that the activation effect is not due to the filler or pozzolanic effect but due to the effect of magnetic fields. Still, the impact of long-term magnetic fields on the processes of cement hydration was not considered yet. Therefore, this work set the task to study the changes in cement hydration and structure formation processes that appear under long-term magnetic impacts.

3 Formulation of the problem

Studies of the hydration products of ordinary and modified by additive EN 197-1–CEM III/A 32.5 N cement were carried out to study the processes of hydration and structure formation of cement with pre-magnetized ferromagnetic dust. The research was carried out by analyzing the binder's hydration products by infrared spectrometry, thermogravimetry, X-ray phase analysis, and electron microscopy.

We have studied the original astringent and hydrated samples at 1, 3, 7, 28, and 90 days. As a magnetized ferromagnetic additive, the dust of the electrostatic precipitators of the sinter production was used. The additive was introduced in an amount of 2% of the weight of the cement.

The studies EN 197-1–CEM III/A 32.5 N cement components chemical composition are shown in Tables 1-3.

Table 1. The chemical composition of the cement clinker.

Components	Content, %
SiO_2	21.80
Al_2O_3	6.04
Fe_2O_3	2.54
CaO	62,72
others	6.90

The quantitative and phase composition of the cement clinker is shown in Table 2.

Table 2. The quantitative and phase composition of the cement clinker.

The data obtained from the research made it possible to carry out a quantitative analysis of the kinetics of hydration of the main components of binders and identify the factors affecting structure formation processes.

4 Statement of material and results

The imposition of weak magnetic fields on a binder during grinding and subsequent storage can affect the cement structure's defectiveness [13-16], significantly affecting its activity [17-19]. Weak magnetic fields decreasing the probability of recombination of dissociated water molecules and increase the concentration of H_3O+ and OH- ions, thereby increasing the chemical activity of water concerning the binder [17]. Having a double effect on the mixing water and the binder itself – the magnetic fields induced by the ferromagnetic additive should change the cement's structure-forming components' strength and affect the cement's strength characteristics stone.

In the early stages, the dynamics of the formation of calcium aluminates significantly affect structure formation. Analysis of the IR spectrum (Fig. 1) in the range of 515-490 cm^{-1} made it possible to obtain a quantitative characteristic of calcium aluminates'

 https://doi.org/10.1051/e3sconf/202128007005

hydration processes in control and modified binders (Fig. 2). The content of non-hydrated calcium aluminates in the modified cement stone-aged 1-28 days is 1.5-2 times less than in the control sample, and at the age of 90 days, it is four times less than in the control sample.

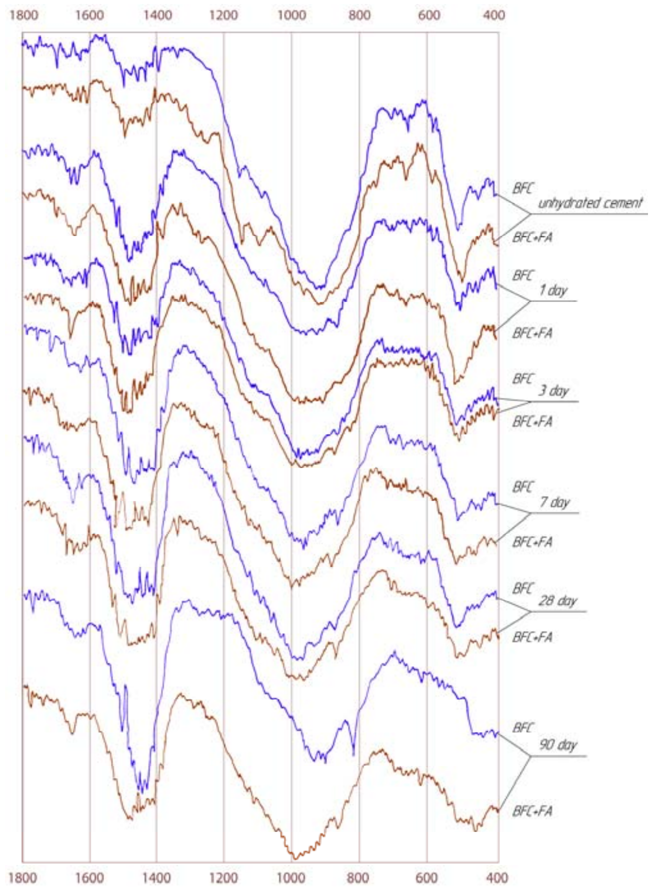

Fig. 1. Infrared absorption spectra of samples from the blast-furnace cement (BFC) and blast-furnace cement with a ferromagnetic additive (BFC+FA) in the initial state and age 1, 3, 7, 28, and 90 days.

When calcium aluminates are hydrated, CAH_6 is formed, identified on DTA (Fig. 3) by endothermic effects at 330-350 °C and 530-570 °C.

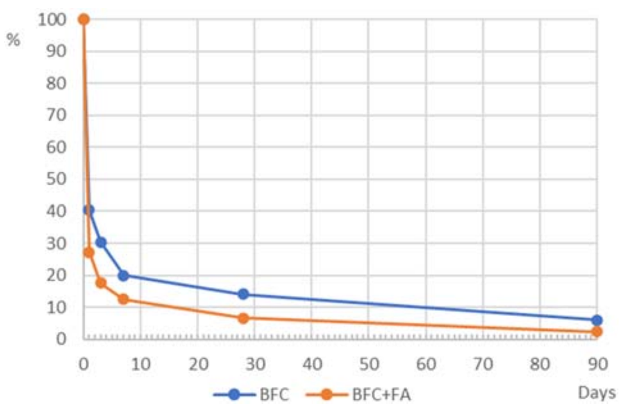

Fig. 2. Kinetics of hydration of calcium aluminates.

The significantly immense value of the cement stone's effects from the modified binder indicates the activating effect of magnetic fields on the process of formation of tricalcium aluminate hexahydrate.

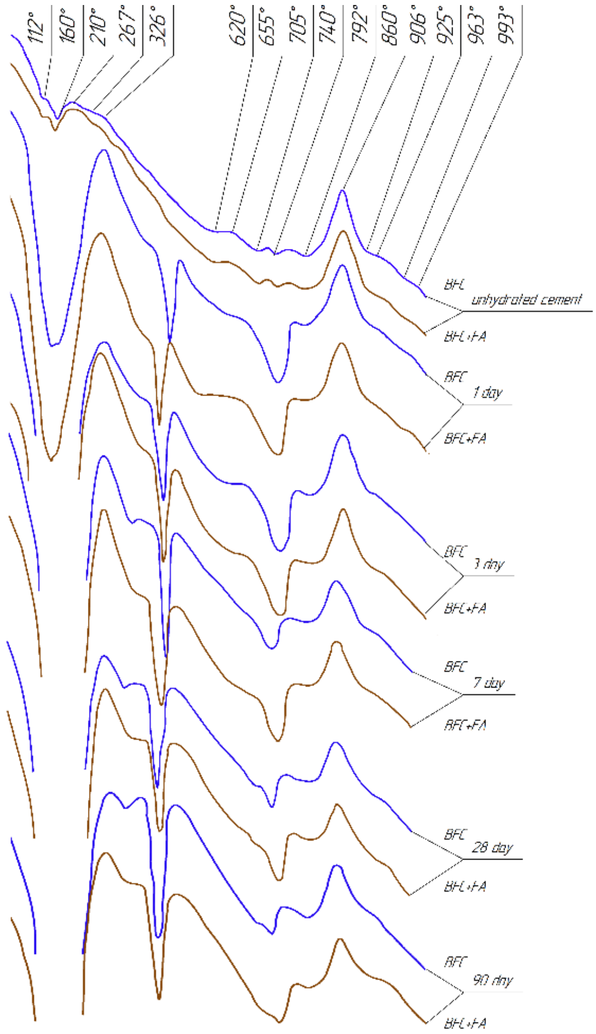

Fig. 3. Curves of differential thermal analysis of samples from the blast-furnace cement (BFC) and blast-furnace cement with a ferromagnetic additive (BFC+FA) in the initial state and age 1, 3, 7, 28, and 90 days.

At the age of 1 day on DTG (Fig. 4) of the modified cement stone, the effect is more pronounced at 140-200 ºC. In subsequent periods, the intensity of the effects of both types of binders leveled. An increase in the IR spectrum with C=1630 cm^{-1} at IR occurs synchronously.

The data indicate the intensive formation of ettringite under the influence of a ferromagnetic additive in up to 1 day and the termination of this process subsequent periods. In a standard binder, ettringite formation observes up to the age of 3 days.

The observed dynamics of the formation of calcium hydro-aluminates and calcium hydro-sulfa-aluminates allow us to conclude that, under the influence of the additive's magnetic fields, constructing the gel's ettringite framework occurs faster and completed within one day. In the subsequent periods, stable six-water tricalcium aluminate mainly formed. This mechanism excludes destructive processes in the late stages of hydration.

The kinetics of hydration of blast-furnace cement is determined by the lime-releasing clinker component –

alite. Acceleration of alite hydration increases calcium hydroxide concentration and intensifies hydration of granulated blast-furnace slag. On the X-ray diffraction patterns (Fig. 5), the process of alite hydration is indicated by a decrease in the height of the peaks with d=0.295; 0.321; 0.327; 0.519 nm.

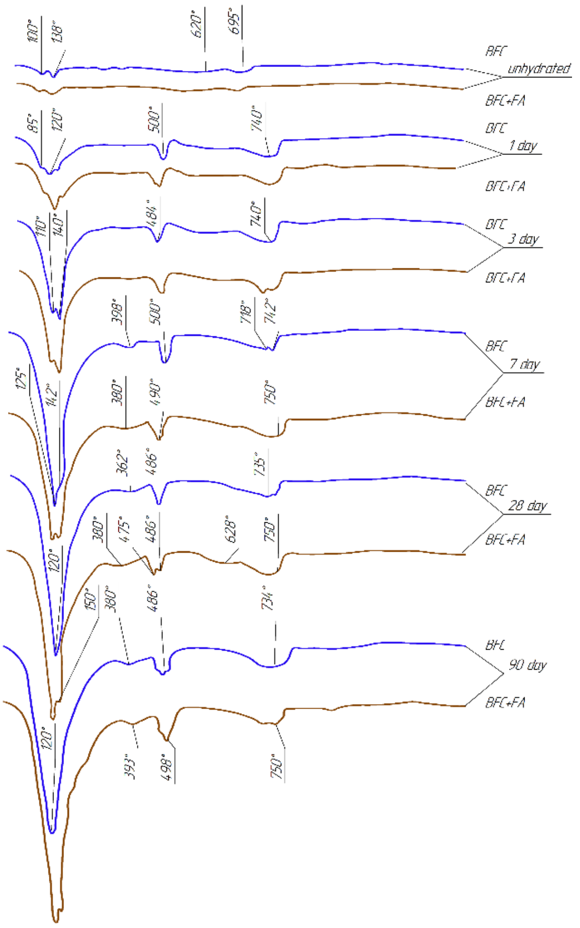

Fig. 4. Curves of differential thermogravimetric analysis of blast-furnace cement (BFC) and blast-furnace cement with a ferromagnetic additive (BFC+FA) in the initial state and age 1, 3, 7, 28, and 90 days.

A decrease in the bands' absorption intensity with C=992 cm^{-1} was observed simultaneously at 875 cm^{-1} in IR spectrograms. The results showed that the kinetics of alite hydration in the modified binder significantly differs from the usual one. At the age of 1-3 days, 13-8 % less is hydrated, and at the period of 7-90 days, 4-5 times the amount of alite is hydrated (Fig. 6).

The slowdown in the hydration of alite at the age of 1-3 days can be explained only by the reaction space's supersaturation with calcium hydroxide and the chemical reaction shift $2Ca_3SiO_5+6H_2O=Ca_3SiO_7{\cdot}3H_2O+3Ca(OH)_2$ towards initial components. The intensive hydration of alite causes an increase in $Ca(OH)_2$ in the period up to the first day. The magnetic fields induced by the ferromagnetic additive cannot influence the diffusion rate of the reaction products. Therefore, in the modified binder, the limiting factor of alite hydration is much faster than in the usual one, diffusion from the Ca^{2+} reaction zone becomes.

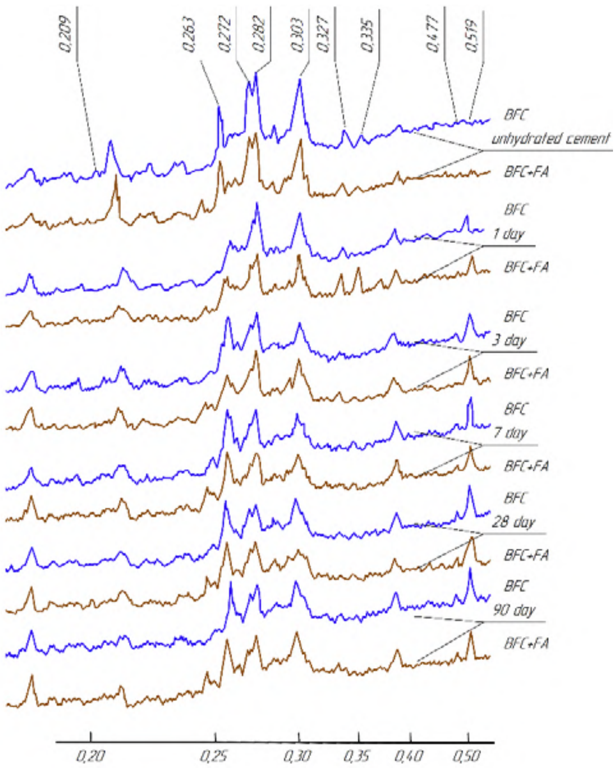

Fig. 5. X-ray patterns of samples from the blast-furnace cement (BFC) and blast-furnace cement with a ferromagnetic additive (BFC+FA) in the initial state and age of 1, 3, 7, 28, and 90 days.

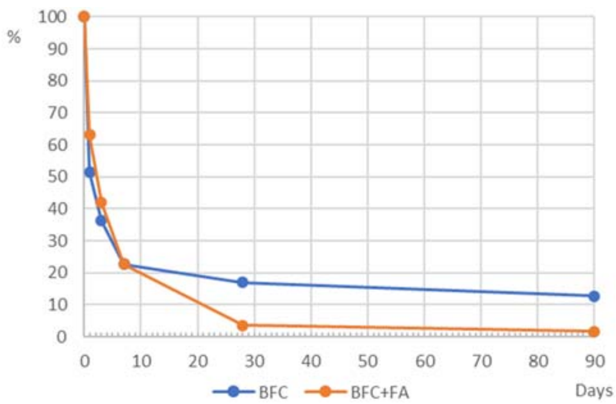

Fig. 6. Kinetics hydration of alit.

An increase in the amount of lime in the gel corresponds to the rise in the peaks with d=0.263; 0.179; 0.168 nm on X-ray diffraction patterns. The strong endothermic effect arising from the dehydration of $Ca(OH)_2$ makes it possible to control its concentration on DTA at t=485º. Analysis of the results confirmed the accelerated formation of lime in a period of up to 1 day. (Fig. 7).

In the gel made of modified cement, calcium hydroxide content is 20 % higher than in the control samples during this period. Although in the subsequent period, the alite degree of hydration under the influence of magnetic fields increases, the content of $Ca(OH)_2$ in the gel becomes 23 % lower than in the original cement at the age of 3 days, by 12 % at the period of 7 days and by 9 % in the age of 28 days. Such dynamics can be explained only by intensifying lime interaction with granulated blast-furnace slag. In this case, a decrease in the IR spectrum's absorption intensity in the region of C=721 cm^{-1} and a reduction in the exothermic effect of the slag's devitrification t=830-870 °C on DTA due observe. Simultaneously, an increase in the height of the peaks with C=648 cm^{-1} should observe, which characterize the content of the slag hydration product, boehmite, in the gel.

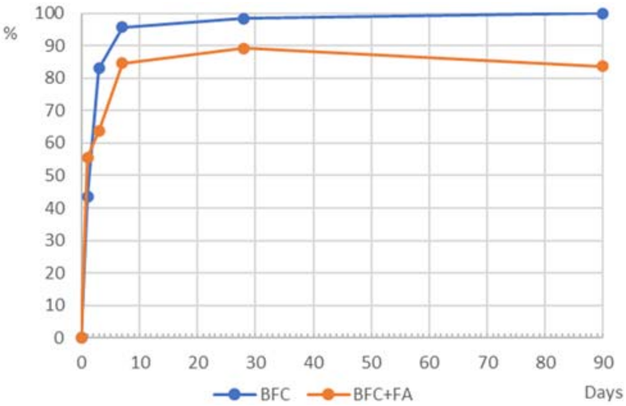

Fig. 7. Kinetics of lime formation.

Analysis of the results confirms that the hydration of granulated blast furnace slag intensified under the action of magnetic fields induced by a ferromagnetic additive (Fig. 8). There is an increase in slag hydration degree by 20 % at three days, 23 % at 28 days, and 59 % at 90 days.

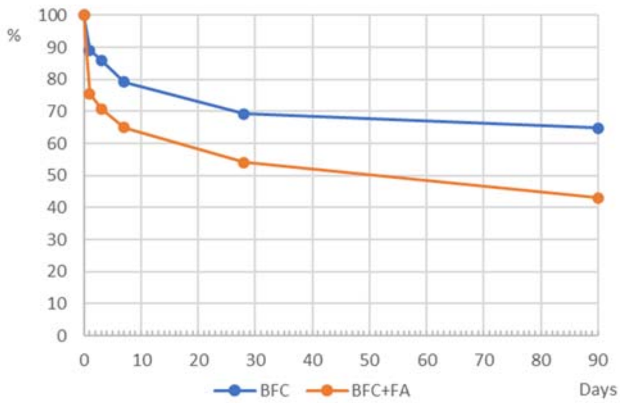

Fig. 8. Slag hydration kinetics.

In ordinary cement, after 28 days of hydration, the slag content practically does not change. In the same period, the content of slag in the modified binder decreases by 30 %. A decrease in the non-hydrated slag content corresponds to an increase in the amount of boehmite in the cement gel (Fig. 9).

In the control cement, boehmite was identified only after three days of hydration, while in the modified binder, characteristic peaks were clearly defined after hydration for one day. Like slag hydration, the process of boehmite formation in the control binder practically stops after 28 days of hardening. On the contrary, long-term continuous exposure to magnetic fields on the modified binder maintains high slag hydration rates later.

In the period 28-90 days, the content of alite in the modified binder is insignificant and amounts to 4-2 % of the original. Such content of C_3S does not provide the slag's hydration with a sufficient amount of calcium hydroxide. The slag's intensive hardening proceeds due to the binding of $Ca(OH)_2$ previously formed reserves. This process reduces the lime content in the modified cement stone of 90 days of age by 65 % (Fig. 7).

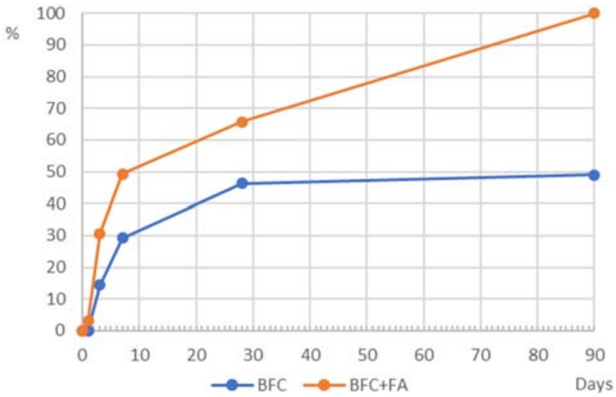

Fig. 9. Kinetics of boehmite formation.

The kinetics of cement stone's carbonization has confirmed a ferromagnetic additive's peculiarities on alite and slag's hydration processes. $CaCO_3$ has pronounced peaks with d=0.303; 0.249; 0.228; 0.209 nm on X-ray diffraction patterns and an absorption band of IR radiation with C=1500-1400 cm^{-1}. Calcite gives a noticeable endothermic effect at t=740 °C on DTA. However, due to the intensive carbonization of lime with carbon dioxide in the furnace atmosphere during heating of the sample, the concentration of $CaCO_3$ overestimated compared to other methods was obtained on DTA.

Analysis of the data obtained shows a correlation between calcium carbonate content and $Ca(OH)_2$. At the age of 1 day in the gel of modified binder calcite by 50 % more than in control one (Fig. 10).

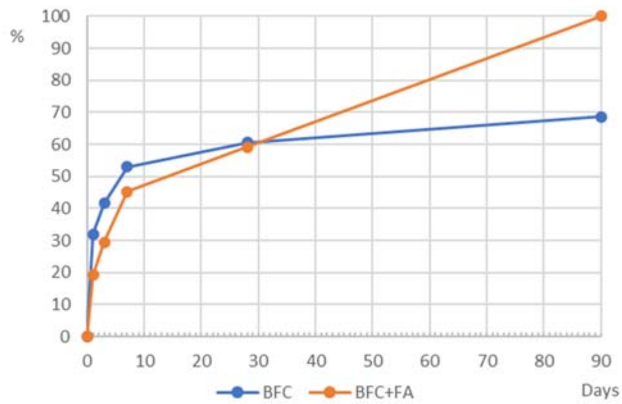

Fig. 10. Kinetics of calcite formation.

During the first ten days, the rate of lime binding with 100 grams of slag is 0.3 grams per day, from 10 to 40 days – 0.1 g/day, and in the period from 40 to 90 days, 0.05 g/day [20]. A continuous decrease in lime absorption by slag with continuous hydration of alite in conventional cement types leads to the accumulation of $Ca(OH)_2$ and, due to carbonization, to increase the $CaCO_3$ content. The accelerated release of lime in the modified binder increases the calcium carbonate content at the initial time. A higher, under the influence of magnetic fields, the rate of lime absorption by slag decreases after 28 days of hydration $Ca(OH)_2$ and "freezes" the concentration of $CaCO_3$.

At the age of 28 days in the modified gel of calcium carbonate, only 5 % more than in the control one. In the control binder, a low rate of lime binding with slag in 28-90 days leads to an increase in the content of calcium carbonate by 58 %. Over the same period, the modified binder's lime content decreases by 6 %, with an increase in the $CaCO_3$ content only by 10 %.

The considered features of the ferromagnetic additive effect on the alite-lime-slag system's hydration allow us to assume the ambiguity of the impact of the modified binder's heat and moisture treatment. In the initial periods of hardening, magnetic fields increase the difference in the lime release rate by alite and its absorption by slag. Heat treatment, increasing the rate of chemical reactions, can further enhance this phenomenon. The excessive rate of hydration products' release increases the unevenness of their distribution in the cement stone, causing destructive processes. Based on this, the combined effect of magnetic and thermal fields can lead to a drop in the cement stone's strength. It is possible to increase the modified binder's tolerance to heat and moisture treatment by expanding its slag. The increased absorption of lime thus promotes the formation of a more stable calcium silicate hydrate.

The revealed patterns make it possible to explain the greater efficiency of magnetic activation for belite types of cement. A smaller amount of lime released during the hardening of belite makes this process less dependent on diffusion. Therefore, the formation process in belite cement under the influence of magnetic fields should be more stable.

Belite hydration is characterized by a decrease in the intensity of peaks with d=0.282; 0.272; 0.269; 0.266 nm on X-ray diffraction patterns and a decrease in the intensity of absorption of IR radiation with C=900; 963 cm^{-1}. The analysis results show that the ferromagnetic additive has an intensifying effect on the process of belite hydration (Fig. 11). The content of non-hydrated belite in the modified binder is less than in control one at the age of 1 day by 12 %, 28 days by 10 %, and at a period of 90 days by 19 %. According to [20], in ordinary cement, the hydration of belite, even after four years of hardening, is only 85 %. According to the analysis data, in the modified binder, already at the age of 90 days, almost all of the belite is hydrated.

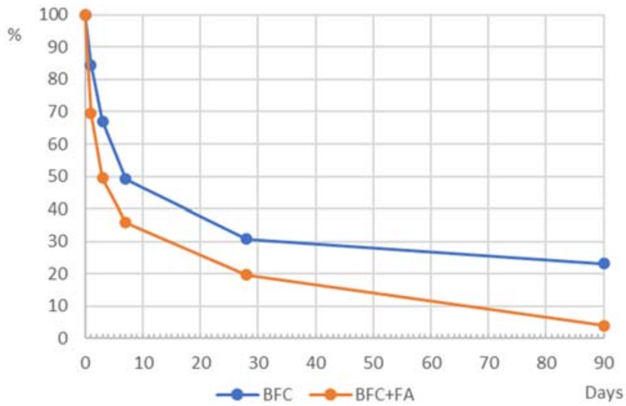

Fig. 11. Kinetics of belite hydration.

Simultaneously with the hydration of belite, there is an increase in peaks d=0.477, 0.335, 0.292 nm, which on the X-ray diffraction patterns correspond to the crystal lattice of hillebrandite. The performed quantitative analysis shows that introducing a ferromagnetic additive into the binder's composition increases hillebrandite content in cement stone of any age approximately twofold (Fig. 12).

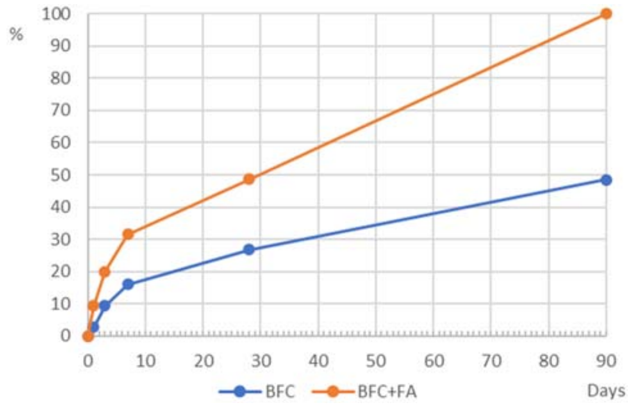

Fig. 12. Kinetics of hillebrandite formation.

The absence of intersections of the lines of the conventional and modified binder on the graph of belite hydration and the chart of hillebrandite formation indicates the monotonicity of the process of belite hydration in the presence of magnetic fields and suggests the absence of malicious processes during their heat and moisture treatment in modified belite binders.

Infrared spectrometry data confirm the results obtained. Silicates have a characteristic infrared absorption band in the 1100-500 cm^{-1} regions. When the binder is hydrated, the region of the most significant absorption of IR radiation is shifted towards higher frequencies, which corresponds to more potent and more rigid bonds in the hydro silicate. The displacement to the high-frequency regions occurs earlier and manifests more intensively on the modified binder's spectrograms. Analysis of the absorption intensity of IR spectra in the range of 1050-800 cm^{-1} made it possible to complete the picture of the structure formation of the silicate phase. Clinker and slag minerals with a chain structure characterized by intense absorption of IR radiation range from 1030-800 cm^{-1}. Research results show a higher degree of silicates' hydration at all hardening stages (Fig. 13). At the age of 3 days, the original silicates in the modified binder are 1.5 times less; at 28 days by 2.5 times, at a period of 90 days by four times. The gel's oversaturation with calcium hydroxide and the slowdown in the hydration of alite explain the change's non-monotonicity in silicates hydration rate in up to 7 days.

The range of 1020-990 cm^{-1} is typical for silicates with a network structure. The spectrograms under consideration allow one to determine the content of crystallized tobermorite in the cement stone (Fig. 14). Analysis of the results shows that the ferromagnetic additive, changing the kinetics of hydration reactions, contributes to increasing the crystallized tobermorite content in cement stone by 1.3-1.4 times.

The transition of hydro silicates from a weakly crystallized to a crystallized state changes the amount of

 https://doi.org/10.1051/e3sconf/202128007005

adsorbed water. On thermograms, this process accompanying a decrease in the endothermic effect at 60-200 °C. Analysis of the areas of endothermic effects on DTA and mass losses on DTG in this temperature range shows a change in the interlayer liquid forming dynamics (Fig. 15).

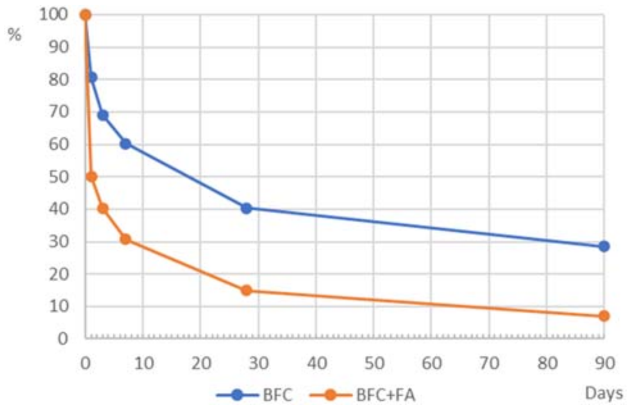

Fig. 13. Hydration kinetics of chain calcium silicates.

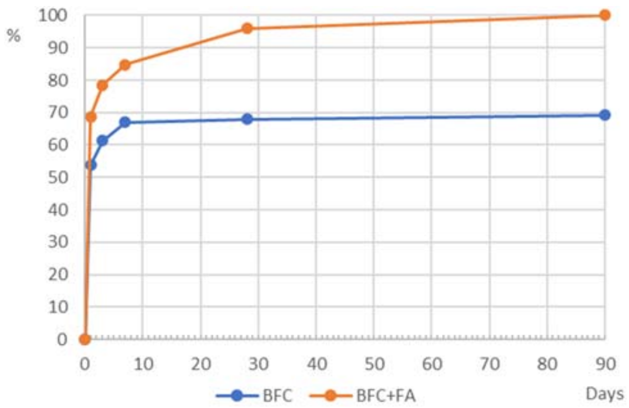

Fig. 14. Kinetics of crystallized tobermorite formation.

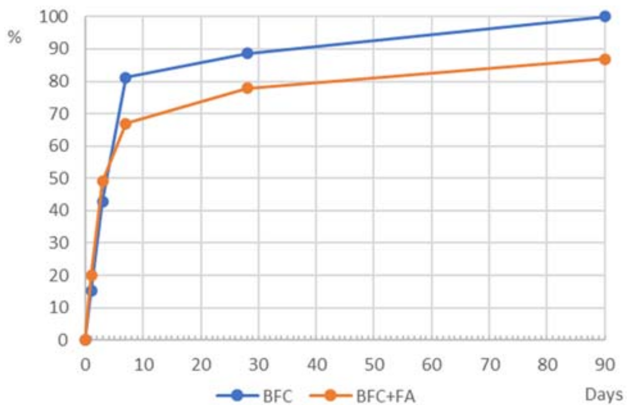

Fig. 15. Kinetics of formation of interlayer water.

The modified binder at the age of 0-3 days has a 5-10 % more, and in subsequent periods, 15-20 % less adsorbed water. Such a change in the binding dynamics of water confirms an increase in CSH formation in the initial period and a higher rate of construction of hydro silicates' crystallization structure in the subsequent period. Caused by the slag's active hydration, the cement gel's lack of calcium hydroxide contributes to forming a larger number of three-layer tobermorite [20], having a lower specific surface area than two-layer ones and adsorbing a smaller amount of water.

Accelerating the crystallization of tobermorite changes the structure of the cement stone. In Fig. 16 and Fig. 17, the cement stone structures spall from the control and modified binder. Lamellar blocks of crystallized tobermorite dominate the modified cement stone. The structure of the modified cement stone is more homogeneous and finer crystalline.

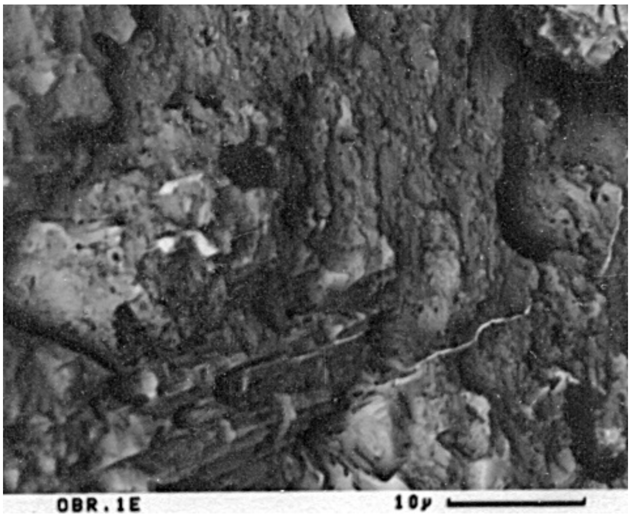

Fig. 16. The structure of blast furnace cement (BFC).

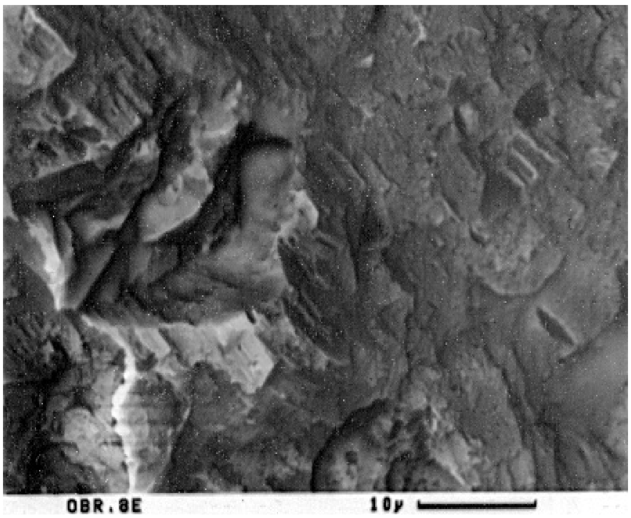

Fig. 17. Structure of cement stone from blast furnace cement with ferromagnetic additive (BFC+FA).

In [21], the orienting effect of magnetic fields on colloidal particles is noting. This phenomenon promotes crystallization and the formation of uniformly oriented crystal structures. The uniform spatial orientation of tobermorite plates observed in the modified cement stone confirms the hydrogel's magnetic fields' orienting effect. The images obtained at 8000× magnification (Fig. 18, 19, and 20) confirm a crystalline structure in the modified cement stone and a weakly crystallized, disordered structure in the control cement stone.

A photograph was taken in the phase contrasts mode (Fig. 19), making it possible to isolate a magnetized dust particle with a darker shade. The "ingrowth" of dust particles into the binder structure is noticeable.

https://doi.org/10.1051/e3sconf/202128007005

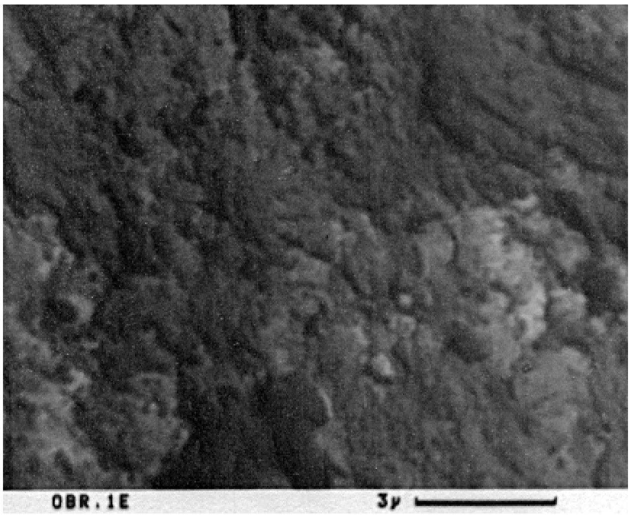

Fig. 18. Structure of blast-furnace cement (BFC).

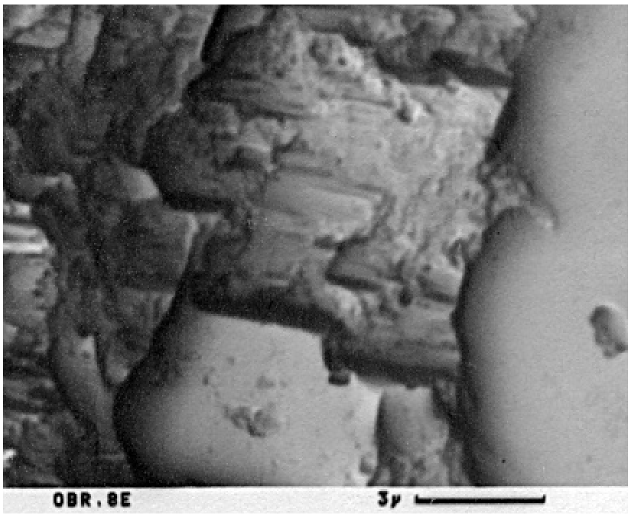

Fig. 19. Structure of cement stone from blast-furnace cement with ferromagnetic additive (BFC+FA).

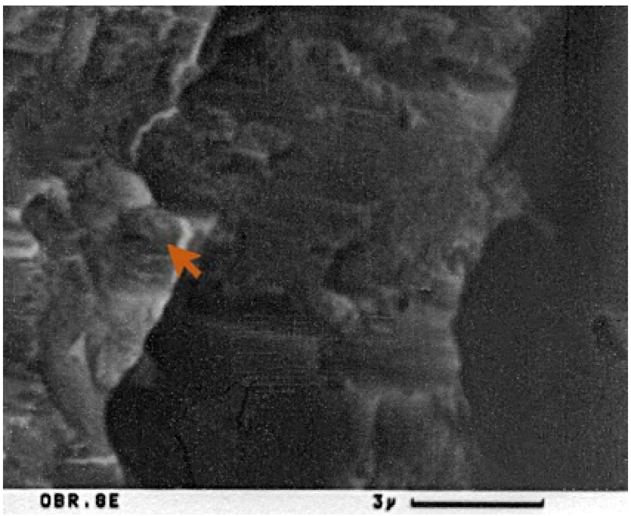

Fig. 20. Structure of a cement stone made of blast-furnace cement with a ferromagnetic additive (BFC+FA). Phase-contrast mode. The arrow marks an ingrown dust particle.

A high degree of hydration of the modified binder reduces the proportion of evaporated mixing water, reducing the cement stone's overall porosity. Fig. 21 shows the surface of a cement stone spall from a non-activated BFC. Numerous microcracks with a length of 50-200 μ and a thickness of 0.5-1 μ are distinguishable on the surface. Microcracks are oriented in different directions and, as a rule, begin at micropores. Numerous micropores are 2-30 μ in size.

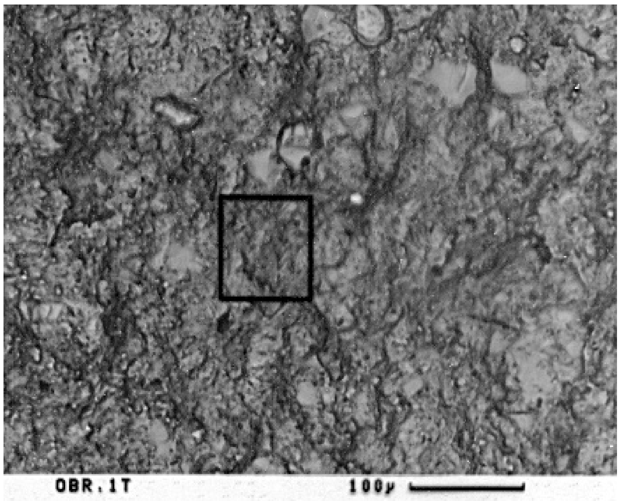

Fig. 21. Structure of blast-furnace cement (BFC).

A smaller number of structural defects distinguishes a cement stone made from a modified binder (Fig. 22, 23). A small number of pores with a size of 0.5-2 μ and the absence of broader.

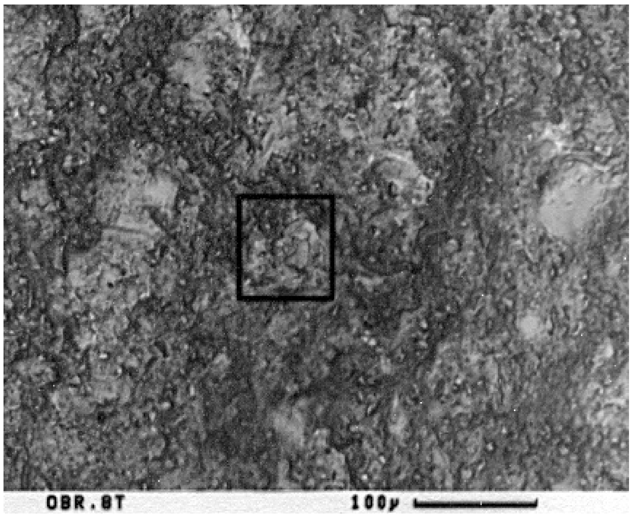

Fig. 22. Structure of cement stone from blast-furnace cement with ferromagnetic additive (BFC+FA).

A decrease in the porosity of a cement stone can be caused by factors other than magnetic fields. A cement stone structure from a binder with a reduced (0.75 %) ferromagnetic additive content was investigated to test this factor's significance. With the microprobe's help, a dust particle was found, and the microstructure in the area adjacent to it was investigated. In the images obtained in the relief mode (Fig. 24) and phase contrasts (Fig. 25), a decrease in the cement stone porosity is observed as the dust particle approaches and the magnetic field strength increases. This confirms the magnetic field strength's

https://doi.org/10.1051/e3sconf/202128007005

influence on the degree of hydration of the binder and the cement stone's porosity.

5 Conclusions

The studies show that the introduction of pre-magnetized ferromagnetic dust into blast furnace cement composition has an activating effect on binder hydration. Activation occurs both in the initial and long periods of hardening. The additive influence on the process of structure formation at a specific point of the cement gel depends on the distance between this point and the dust particle and the magnetic fields' intensity at this point.

It proved that under the influence of magnetic fields, intensive hydration of alite in up to 1 day causes supersaturation of the gel with calcium hydroxide, which slows down the hydration of alite for a period of up to 7 days. We found that the second increase in the hydration rate of alite after seven days of age is caused by the intensive, under the additive, absorption of lime by slag. It determined that the ferromagnetic additive, intensifying the process of slag hardening, increases the proportion of hydrated slag by 1.5-2 times.

The investigation established that the reduced release of lime during hardening determines the monotony of the increase in the rate of hydration of belite in the modified binder. It determined that the most significant activating effect on C_2S hydration be achieved after 28 days of hardening.

Studies proved that the ettringite framework's formation in the modified binder's gel is completed within one day. In subsequent periods, the hydration of aluminates occurs mainly due to the formation of tricalcium aluminate hexahydrate, which excludes destructive processes in the late periods of binder hardening.

It founded that under the impact of a ferromagnetic additive, the crystallization of hydro silicates in the modified binder increases. It determined that magnetic fields have an orienting effect on the direction of hydro silicate crystals' growth, which leads to a decrease in the porosity and defectiveness of the cement stone structure.

Abstract. In connection with the growing need for saving natural resources used in aggregates for concrete, the importance of lightweight structural aggregates obtained from production waste is continuously increasing. Lightweight structural concretes on porous aggregates can significantly reduce own weight of structures, make it possible to manufacture larger structures, reduce transport costs, and improve the thermal insulation and acoustic properties of enclosing structures. The use of waste from the mining and metallurgical industry to produce construction materials significantly reduces environmental pollution. The article is devoted to studying the possibility of using wastes from the mining and processing industry of enterprises of the Kryvyi Rih iron ore basin to produce lightweight porous aggregate. The paper presents the results of studies of the effect of the charge's granulometric composition, the quantitative content of the raw mix components, and the temperature of heat treatment on aggregate quality. The most suitable raw material mixture for artificial aggregate has been determined. The results of X-ray diffraction thermographic analysis of raw granules are presented. The influence of technological factors on the aggregate density and strength has been studied using mathematical modeling. The obtained equations made it possible to reveal the regularities of the raw mixture's components and temperature for the optimal aggregate density and strength. The results of studying the structure and porosity of the developed aggregate are presented. The results of X-ray thermographic analysis of the aggregate explain the mechanism of pore formation in the pellets. The basic physical and mechanical properties of the obtained aggregate are investigated, particularly attention pairing to the study of the aggregate's contact zone with the cement stone.

1 The problem and its relationship with scientific and practical tasks

One of the main tasks in sustainable construction development is reducing the mass of buildings and structures. One way to solve this problem is to use lightweight and lightweight concrete on porous aggregates. Despite the constant increase in lightweight concrete structures, their share does not exceed 30% of reinforced concrete volume.

The need to expand the production of lightweight concrete products is due to the ability to reduce the mass of buildings by 30-40%, reduce the construction time by 20%, reduce transport costs by 30-40%, and significantly improve the thermal and acoustic properties of enclosing structures [1-5]. The considered advantages can significantly reduce the consumption of resources for constructing buildings and reduce the number of harmful emissions into the environment.

There are practically no areas of construction where porous aggregate concrete cannot successfully replace heavy concrete. Traditionally, lightweight concrete using as thermal insulation and structural-thermal insulation materials. However, in the total volume of building structures, enclosing structures make up only 25-30%, and load-bearing systems - 70-75%; therefore, the need to expand structural concrete production with porous aggregates are put forward in the first place. The release of load-bearing structures from lightweight and lightweight concrete is primarily constrained by the absence or shortage of suitable and durable porous aggregates. Most of the porous aggregates are used only for the production of building envelopes. Therefore, artificial porous aggregates from local raw materials significantly waste from the mining and metallurgical industries are of exact importance.

Mining and processing plants of Ukraine annually

* Corresponding author: lev1351ua@gmail.com

store more than 130 million m^3 of sludge. Only in the Kryvyi Rih iron ore basin, more than 2 thousand hectares of agricultural land are occupied by dumps. Part of the enrichment waste, with a particle size of more than 0.14 mm, is used as a sand and crushed stone. However, a significant amount of waste has a particle size of less than 0.14 mm, not currently used. Therefore, developing a technology for obtaining sustainable porous aggregates for concretes using finely dispersed waste from mining and processing plants and concretes based on them continues to be an urgent scientific, technical, and social task.

2 Development of charge compositions and heat treatment mode

The research aims to develop optimal compositions of new porous aggregates made from the waste of mining and processing plants and study these aggregates' properties.

The selection of the optimal composition of raw materials for the porous filler included an analysis of the influence of the charge and additives' design and their granulometric composition on the final product's quality.

Dry mixtures contained:

- crushed and not crushed sludge (grains with a size of 1.25...0.14 mm);
- not crushed sludge with the addition of crushed shale;
- not crushed and crushed sludge with the addition of crushed shale;
- crushed sludge and crushed shale.

Dosing of the dry components of the charge carried out by weight. The content of crushed sludge and shale is taken as a percentage of the total dry ingredients. The content the rate of consumption of alkali silicate is taken from the total weight of the charge.

The mixture was granulated in a disk granulator to form granules with a diameter of 5...20 mm. Liquid glass is fed into the pelletizer using a spray gun.

The molding of the raw granules was carried out at different density values of alkali silicate (1.30...1.45 g/cm^3), which provided the introduction of the required amount of its solid substance into the charge. This approach made it possible to reveal the pattern and nature of the influence of the consumption of alkali metal silicate on the porous filler's properties. Raw granules' burning was carried out at 950, 1050, and 1150 °C for 5, 10, 15, and 20 minutes. Further analysis of the results showed that firing longer than 10 minutes had no significant effect on the studied parameters.

The burnt granules' testing results from a raw mixture with crushed sludge in its proportion shown in Fig. 1. The obtained results show that if alkali silicate and the amount of ground sludge in the charge increases, the average density of aggregate granules decreases. However, it is impossible to obtain an aggregate with an average density of less than 1.5 g/cm^3 due to the resulting liquid phase's small amount. The amount of the liquid phase largely depends on the content of fine particles in the mixture. The amount of ground sludge did not exceed 20%, and the larger grains did not take an active part in creating the pyroplastic melt; they dissolved only partially.

Adding a part of crushed shale to the slurry made it possible to obtain an aggregate with a lower average density than in the previous case. This dependence showed in Fig. 2. A decrease in filler granules' average density with the same fraction of the crushed charge (Fig. 1) occurs due to an increase in the liquid phase amount. This is because liquid glass forms more melting eutectics with shale minerals and more intense gas evolution occurs.

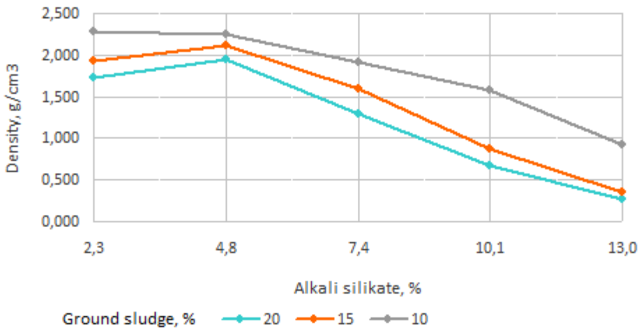

Fig. 1. Influence of the content of ground sludge and the flow rate of alkali silicate on the aggregate's front density.

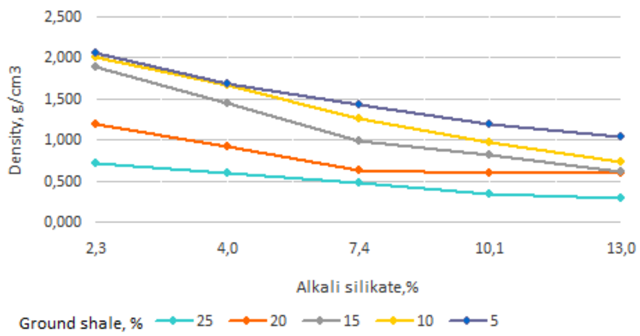

Fig. 2. Influence of ground shale and alkali metal silicate content on average aggregate density.

Studies have been carried out to study the content of crushed sludge and shale for the aggregate average density. These studies' results are shown in Fig. 3 and show that aggregate granules' average density decreases almost linearly, increasing alkali silicate consumption.

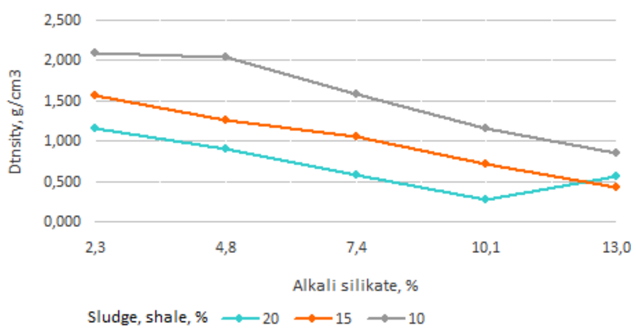

Fig. 3. Influence of the content of ground sludge, shale, and alkali silicate consumption on the average density of the aggregate.

 https://doi.org/10.1051/e3sconf/202128007006

However, with a 15% content of crushed sludge, shale, and alkali silicate consumption of more than 10%, an increase in aggregate granules' average density is observed. A decrease explains this in the melt's viscosity and the process of compaction rather than porization. The combined effect of the milled components on the aggregate granules' average density is greater than that of each separately.

Previous studies have shown that using a mixture containing unmilled sludge and shale results in low-strength granules with low porosity and high average density. Therefore, all further studies were carried out only on mixtures with ground components. The results showed in Fig. 4 and 5.

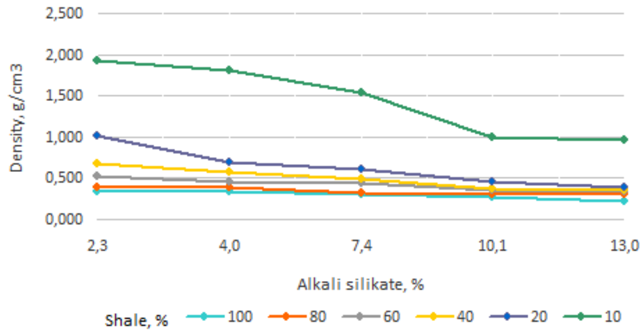

Fig. 4. The influence of alkali silicate consumption and the composition of the charge on the aggregate's average density.

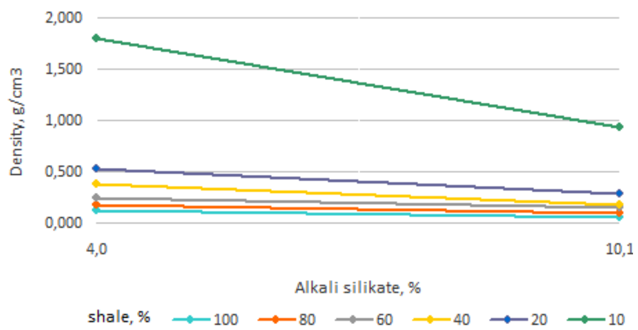

Fig. 5. Influence of the composition of the charge and the consumption of alkali silicate on the aggregate's average density.

Dependencies show that the most intensive decrease in average density occurs when there is up to 40% shale in the charge. A further increase in the shale amount reduces the average density slightly, but the granules' strength sharply decreases, and the pores increase due to increased gas release. Intense and excessive release of gaseous products does not improve the porization process but causes the formation of large interconnected pores, passing into cavities and open pores.

X-ray phase analysis of raw granule powders, dried to constant weight, showed the presence of the following minerals:

– β-SiO_2 (β-quartz);
– $FeFe_2O_4$;
– α - Fe_2O_3;
– $Al_2O_3 \cdot 2Si0_2 \cdot 2H_2O$ – kaolinite;
– hydromica;
– $K_2O \cdot Al_2O_3 \cdot 6SiO_2$ – potassium feldspar (orthoclase);
– $K(Mg, Fe)_3$ $[\cdot AlSi_3O_{10}] \cdot (OH, F)$;
– $K \cdot Al_2 \cdot [AlSi_4O_{10}] \cdot (OH)_2 \cdot nH_2O$ – illite;
– chlorites with an approximate composition of $Mg_5Al \cdot [AlSi_3O_{10}] \cdot (OH)_8$;
– $CaMg$ $(CO_3)_2$ – dolomite;

Differential thermal analysis of raw granule powders showed (Fig. 6) the presence of endothermic effects at a maximum of 140, 448, 584, and 772 °C. The total weight loss upon calcination up to 800 °C was 8.11%. The endothermic effect at a temperature of 140 °C is associated with removing adsorption water from clay minerals: kaolinite, monothermite, and illite close to kaolinite.

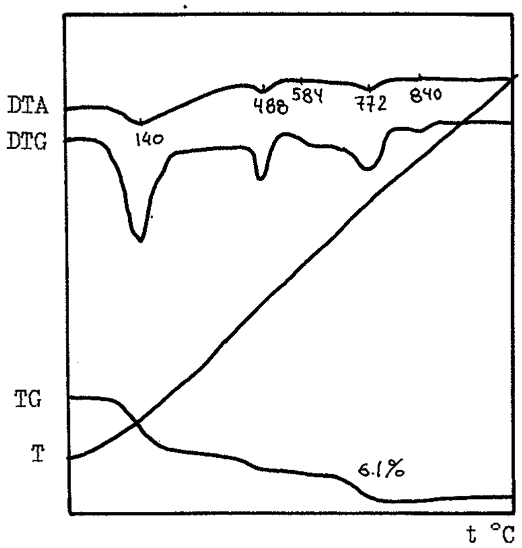

Fig. 6. Thermogram of raw granules.

The endothermic effect at a maximum temperature of 448 °C is associated with removing constitutional water from the crystal lattice of minerals: kaolinite, monothermite, followed by the crystal lattice's destruction.

A small endothermic effect at a maximum temperature of 584 °C is associated with removing constitutional water from the crystal lattice of minerals: illite, hydromica, and chlorite. The endothermic effect with a maximum of 772 °C is associated with dissociation of $CaCO_3$ and dolomite and the destruction of chloride's crystal lattice.

The blurred endothermic effect at a maximum temperature of 840 °C is associated with destroying the crystal lattice of hydromica and illite.

Since previous studies have established that the most suitable for obtaining a porous aggregate is a crude mixture consisting of crushed sludge, crushed shale, and water glass, these mixtures have been used to study the influence of technological factors on the properties of the porous aggregate. The research objective is to obtain mathematical models expressing the aggregate's average density and strength on the leading technological factors. The mathematical planning method, followed by mathematical and statistical processing of the results, was used to reduce the number of experiments.

A three-factor experiment at two levels is planned in

 https://doi.org/10.1051/e3sconf/202128007006

the work. The variables are X_1 – the content of ground shale as a percent of the total mass of dry components; X_2 – consumption of liquid glass as a percent of the total mass of the charge; X_3 – firing temperature °C. Since firing for more than 10 minutes did not significantly affect the study's parameters, firing the granules was 10 minutes and not taken as a variable.

The levels and intervals of variation of the selected factors are shoved in the table. 1.

Table 1. Levels and intervals of variation.

Code	Code value	Value of factors		
		X_1	X_2	X_3
Main level	0	30	8.0	1050
Variation interval	X_1	10	1.4	100
Upper level	+	40	9.4	1150
Lower level	-	20	6.6	950

After statistical analysis, the equations have the following form:

$$Y_\gamma = 1.285 - 0.098X_1 - 0.570X_3; \quad (1)$$
$$Y_r = 108.13 - 24.13X_2 - 80.32X_3 \quad (2)$$

When checking the suitability of the above equations by Fisher's criterion, they all became adequate.

Analysis of equations (1) and (2) shows that within the limits of variation of the variables, the burning temperature, and shale consumption has the most significant effect on the average density of the aggregate, and the effect of the burning temperature is six times greater than the consumption of shale. As the strength of the aggregate decreases, the burning temperature and the alkali silicate consumption increase.

Fig. 7, 8 shows a graphical interpretation of the obtained dependencies.

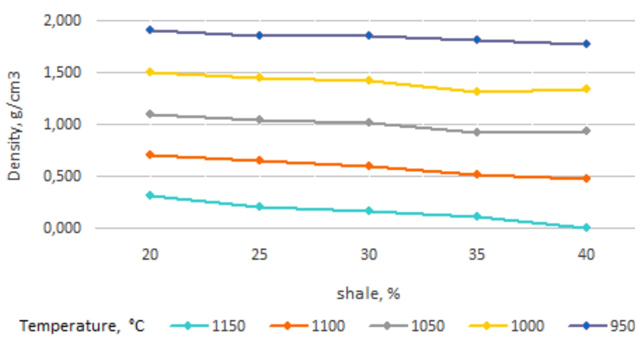

Fig. 7. Influence of technological factors on the average density of the aggregate.

3 Properties of porous waste aggregate

To obtain a complete characterization of a material and to identify its behavior in concrete, detailed studies of its properties, structure, and phase composition are required.

Such studies are essential because of the specifics of the raw materials used, allowing us to assume that we have an aggregate that differs from other aggregates similar in technology and shape in terms of structure.

The aggregates obtained both in a laboratory and in industrial conditions were subjected to research. The general view of the porous aggregate granules from the MBC wastes showed in Fig. 9.

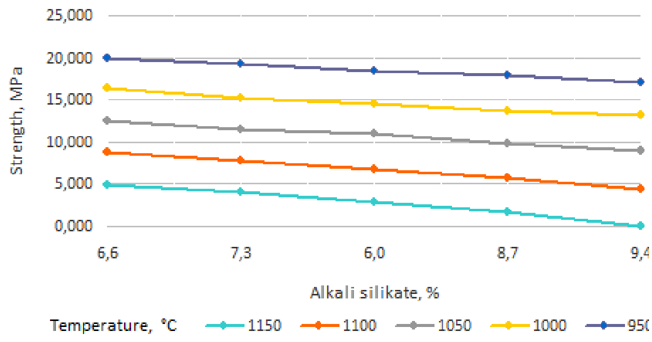

Fig. 8. Influence of technological factors on the strength of the aggregate.

Fig. 9. General view of aggregate granules, d=25 mm.

The samples of the obtained porous aggregates of dark brown color differ little from each other and have a large-porous structure with cavities. The pores are generally round, 250-1000 microns in size. The surface of the aggregate is partially melted and differs from the inner layers in its lower porosity. The absence of a dense sintered crust on the new aggregate's surface is expected to increase adhesion to the cement stone, ultimately leading to increased concrete strength.

The images were taken with a Scanning Electron Microscope (SEM) to show a porous aggregate structure from MBC wastes (Fig. 10). There is a different size of porosity of the material. The pores have a smooth surface, and the surface of the chipped partitions between the pores is glassy (homogeneous).

The nature of pore formation is the peculiarity of the new aggregate structure. The swelling of the pyroplastic melt causes this process due to the release of CO2 from the pellet volume.

X-ray analysis of granules burnt at a temperature of 1000 °C (Fig. 11 a) shows a significant decrease in β-lines of quartz, the appearance of lines of mullite, corundum, albite, nepheline and minerals of zeolite structure:

– mullite – $3Al_2O_3{\cdot}2SiO_3$ with d/n=53; 38; 35; 33.8; 28.8; 26.8; 25.4; 24.9; 23; 22; 21.2; 16.9; 15.2 mμ;
– corundum – α-Al_2O_3 with d/n=34.8; 25.5; 24; 20.8; 17.4; 16.0; 15.4; 15.08 mμ;
– albite – $Na_2O{\cdot}Al_2O_3{\cdot}6SiO_z$ – high-temperature modification with d/n =32.1; 25.1 mμ;
– nepheline – $Na_2O{\cdot}A1_2O_3{\cdot}SiO_2$ with d/n = 70.7; 40.4;

31.8; 26.8· mμ;

– zeolites with d/n = 26.1; 16.68; 15.07·mμ.

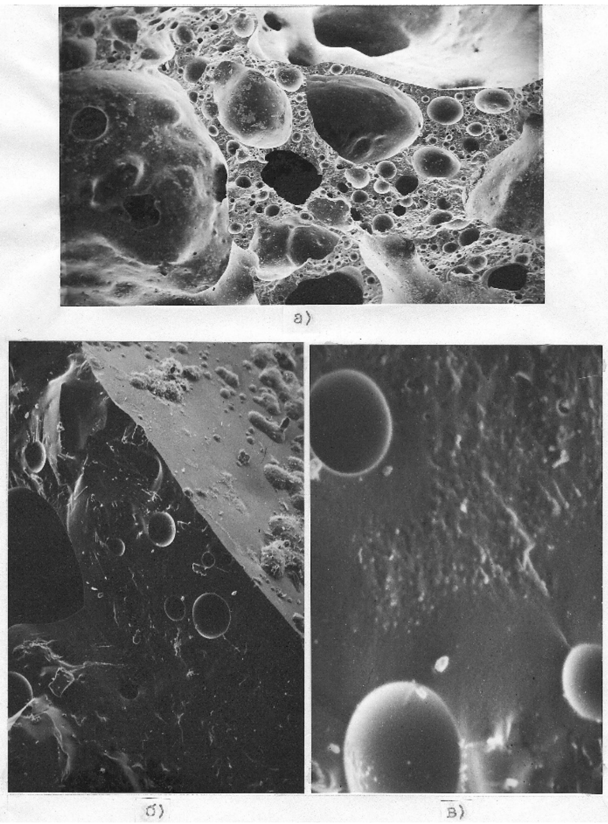

Fig. 10. Aggregate structure image with SEM: a) general view, magnification 45x; b) chipped partition, magnification 700x; c) chipped partition, magnification 3000x.

Thermographic studies of the raw granules burnt at a temperature of 1000 °C showed (Fig. 12) the presence of the weak endothermic effects with maximum temperatures of 58, 249, 590, and 800 °C.

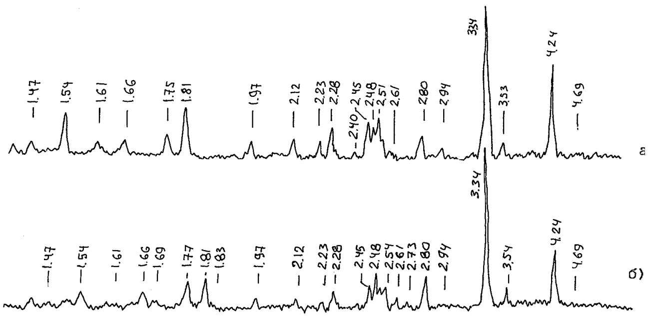

Fig. 11. Radiograph of the burnt masses: a) burnt at 1000 °C; b) burnt at 1150 °C.

All four weak endoeffects are probably associated with the polymorphic transformations in an insignificant part of silica from its total amount into phase varieties of quartz sequentially with a decrease in the temperature of endoeffects: α-tridymite → α-quartz → β-quartz → β-cristobalite → γ-tridymite. According to the X-ray phase analysis, β-quartz remains the most representative modification. When burnt, the lines of γ-tridymite with d/n=43.9 appear; 41.2; 37.3; 24.9; 16.9; 16.2; 15.9; 15.28 mμ.

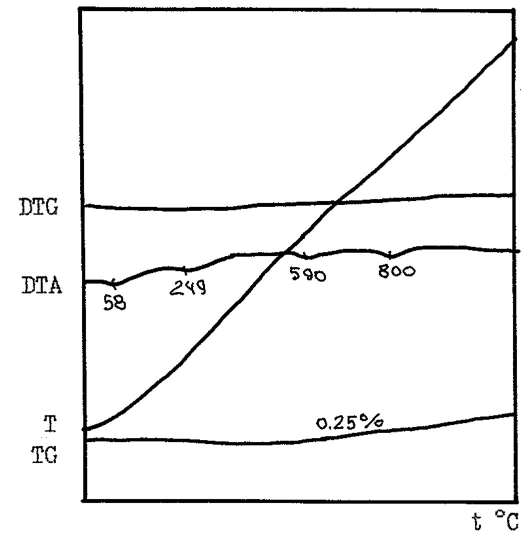

Fig. 12. Thermogram of the aggregate burnt at the temperature of 1100 °C

When calcinated up to 800 °C, the weight loss was 0.25%, which is within the experimental error. Perhaps such weight loss is due to the adsorbed water after burning. This fact may correspond to a weak endothermic effect at a maximum temperature of 58 °C.

An increase of the burning temperature to 1150 °C (Fig. 12 b) leads to an increase in mullite, corundum, γ-tridymite, and aluminosilicates of the zeolite structure and albite.

According to the methodology of State standard GOST 9758-2012 (Porous inorganic fillers for construction works, Test methods), the research was carried out. An artificial porous aggregate from MBC wastes obtained in experimental industrial conditions were tested. The test results are presented in the table. 2.

For pilot production of aggregate used a mixture of mining waste and shale in a ratio of 4:1 by weight; the consumption of liquid glass is 8% of the weight of dry components and firing temperature 1100 °C for 15 minutes.

As table 2 shows, the tested aggregate meets the requirements of GOST 9757-90 (Artificial porous gravel, crushed stone, and sand. Technical conditions) and belongs to the highest quality category.

Table 2. Physical and mechanical properties of porous aggregate from MBC wastes.

Indicators	Units of measurement:	fraction, mm		
		5-10	10-20	20-40
Density	g/cm^3	2.95	2.95	2.95
Bulk density	kg/m^3	1150	1100	1000
Average density of grains	g/cm^3	1.93	1.90	1.89
Porosity of grains	%	39.0	42.0	45.0
Moisture	%	0.70	0.68	0.74
Water absorption per hour	%	5.20	6.50	8.80
The compression strength of the aggregate in the cylinder	MPa	6.50	5.80	4.96
Softening coefficient	–	0.98	0.96	0.94
Grain shape coefficient	–	1.15	1.20	1.25
Frost resistance	cycle	>100	>100	>100

The strength of lightweight concrete is not only a function of the consumption and strength of the binder, the consumption of porous aggregates, but it is also determined by the structure and composition of the contact layer between them. Due to the difference between the obtained porous aggregate from other known ones, the processes occurring at the border with the cement stone can proceed differently and lead to hydrated compounds with different specific surface areas and porosity. Ultimately, this will lead to a change in the binder's porosity, concrete structure, and physical and technical properties.

A cement stone's contact zone with a large porous aggregate (Fig. 13) has the form of a winding line exactly repeating the granule relief, providing a tight and robust contact.

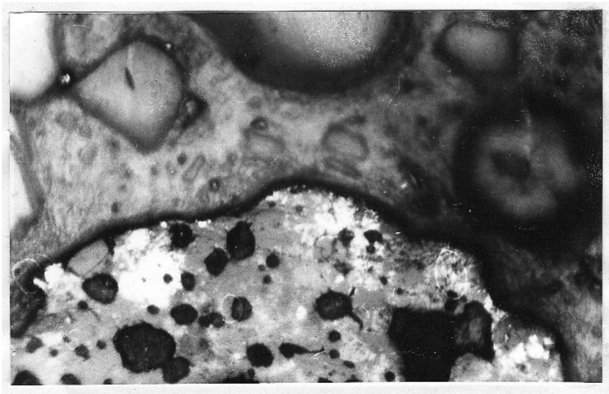

Fig. 13. Contact zone of new porous aggregate with cement stone.

The thermogram of the cement stone from the intergranular space (Fig. 14 a) showed the presence of four endoeffects with a maximum temperature of 155, 521, 663, and 818 °C.

The temperature of 155 °C corresponds to the dehydration of the high sulfate form of calcium hydrosulfoaluminate in the presence of gypsum or low-basic calcium hydrosilicates in the binder. A temperature of 521 °C corresponds to the dehydration of tobermorite-type hydrosilicates, and 818 °C corresponds to the decomposition of $CaCO_3$. When calcinated up to 400 °C, the total weight loss was 11%.

Thermographic studies of the contact zone, burnt granules (the binder) showed (Fig. 14 b) the presence of seven endoeffects with temperatures at maximum: 110, 228, 480, 584, 712, 784, 849 °C. The endothermic effect at 110 °C corresponds to the dehydration of the three-sulfate form of calcium hydrosulfoaluminate or calcium hydrosilicates of a hydrating binder; 480 °C corresponds to the dehydration of Ca $(OH)_2$; 712 °C – dehydration of tobermorite type hydrosilicates – CSH (B); 784 °C – $CaCO_3$ dissociation. At the maximum temperatures of 849, 584, and 228 °C weak endoeffects correspond to silica transformations into its polymorphic modifications described above.

In the contact zone, water was sucked into the granule body. Therefore, the weight loss upon calcination up to 800 °C was 1.5%. With a lack of water, hydration hardening occurs in the binder particles' surface layers adjacent to the granule. The conditions for forming hydrosilicates of the tobermorite type of a high crystallization degree are created (the temperature shift of the maximum endothermic effect from 633 °C for the binder 712 °C in the contact zone).

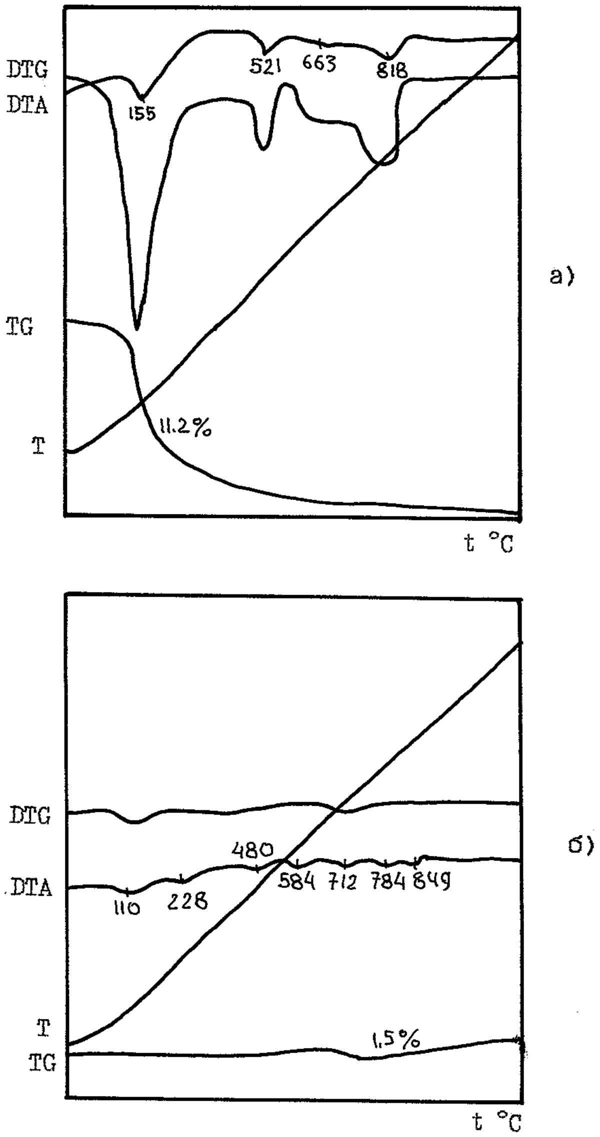

Fig. 14. Thermogram of cement stone: a) in the intergranular space; b) from the contact layer.

The microhardness measurement method was used to study the micro-strength properties of the contact zone. The results have shown that the microhardness of the aggregate (9000...11000 MPa) exceeds the microhardness of the cement stone in the contact zone (4000...6000 MPa), and the microhardness of the contact zone is higher than that one of the cement stone in the intergranular space (1500...2000 MPa).

5 Conclusions

– To obtain a porous filler, the most optimal is raw mixtures containing 20...40% shale and 6…10% liquid glass, fired at a temperature of 950...1150 °C.
– Mathematical models have been obtained that reflect the influence of technological factors on the volume, density, and strength of porous aggregates from the

waste of mining and processing plants.

- The physical and mechanical properties of the obtained porous filler, characterized by high mechanical strength, have been determined. The filler meets the requirements of the standards and belongs to the highest quality category.
- The filler has a porous structure with a predominance of pores 250-1000 μm and is composed of mullite, corundum, albite, nepheline, and minerals of zeolite structure.
- In the contact layer between the aggregate and the cement stone, a chemical interaction occurs with the formation of hydrosilicates of the tobermorite type, contributing to strengthening and intergrowth with the cement stone.

Abstract. The report presents the results of research on the use of composite material - fiber-reinforced concrete for the manufacture of centrifugal pump bodies. The, optimal composition of fiber-reinforced concrete with the required strength characteristics has been established. The method of casting a pump body and the results of industrial tests to determine the technological parameters of a centrifugal pump are presented. The results obtained showed that fiber-reinforced concrete bodies have an advantage over metal ones and can be recommended for use in mechanical engineering in the manufacture of centrifugal pump bodies.

Introduction

In the process of the development of the mining and metallurgical and oil and gas industries, the requirements for the quality of the products were increased, as well as the environmental and safety requirements for equipment became more stringent.

All these factors led to the emergence of new technologies for processing raw materials, the technological parameters of the equipment began to change, and new chemical liquids, more aggressive not only with respect to the material being processed, but also to the working bodies of the equipment, began to be used in technological processes.

This caused the following problems when operating the pumping equipment:

- the appearance of corrosion and erosion of pump elements in direct contact with the pumped corrosive liquid;

- the presence of solid inclusions in the pumped liquid led to abrasive wear of the pump flow path;

- as follows from the above, during the operation of the pumps, there is the appearance of hydraulic shocks during the operation of the pump and an increase in wear of the housing elements, which led to thinning of the housing walls, as well as an increase in vibration of the entire unit and a reduction in the service life of the bearings due to the growth of cavitation processes.

Based on the analysis of the main problems of the operation of pumping units, standards for the manufacture of pumping units were developed, which made it possible to unify the requirements for equipment and bring reliability indicators to a single denominator [1, 2].

Modern standards rather strictly regulate the types of materials, depending on the types of pumping equipment used. Pump elements that have direct contact with an aggressive liquid are practically not made of gray cast iron, since it is not resistant to aggressive liquids, as a result of which there is a rapid destruction of metal and frequent replacement of elements is required, which worsens the reliability of the pump and increases operating costs [3, 4]. For pumping corrosive liquids, materials with the required strength and resistance against corrosion and erosion are used, as well as special alloys that can withstand high temperatures of the pumping liquid. For example, high-alloy chromium-nickel steel is used for pumping acidic liquids. Depending on the discharge pressure, the properties of the pumped material and its aggressiveness, carbon steels and aluminum alloys are also used. Practice shows that with an increase in wall thickness, porosity forms in cast iron bodies. In this regard, the bodies are cast from carbon alloys. Considering the dimensions and weight of the pumping equipment of the mining and processing enterprise, then considerable funds are spent on casting the pump body [5,6].

One of the ways out of this situation is the use of construction materials with a low cost, but meeting the requirements of the conditions for the safe operation of equipment. This material includes fiber concrete.

Fiber concrete is a fine-grained material, one of which is a reinforcing filler. These composites are very promising for use in mechanical engineering, in particular, in the manufacture of body parts for pumping equipment [7].

Modernization of centrifugal pump casings by replacing materials with composite materials is very important.

Currently, fiber-reinforced concretes are widely used in the production of building materials and have been

* Corresponding author: baskanbaeva@mail.ru

thoroughly investigated. However, there are practically no works related to the study of the use of these materials in mechanical engineering, especially for the manufacture of parts of technological equipment [8-10].

Research work on the use of fiber-reinforced concrete as a material for the manufacture of centrifugal pump casings was carried out at the Kazakh National Research Technical University named after K.I. Satpayev. These studies were carried out in a wide range from the selection of a rational composition of fiber-reinforced concrete to testing a cast body sample in an industrial environment. This article presents the main results of these researches.

Methods

To create a composite material, theoretical and experimental studies were carried out. Theoretical studies included a patent-literature review on composite materials, including fiber-reinforced concrete, as well as on existing methods of mixture preparation and casting technology for body parts. In experimental studies, the optimal composition of the mixture was determined, the mechanical properties of fiber-reinforced concrete were tested [5], the casting technology of the body was worked out and the industrial test of the finished body made of fiber-reinforced concrete was carried out. To conduct an experimental study, a method was developed for determining the mechanical properties of fiber-reinforced concrete and a method for conducting tests on an industrial bench in the conditions of JSC "Almaty Heavy Engineering Plant". The results of experimental studies were processed according to the standard method of mathematical statistics. Based on the research results, a comparative assessment of pump casings made of fiber-reinforced concrete and metal is given.

This composition of polymer concrete is selected based on a number of requirements.

1. The need to obtain a mixture with a mobility of 8 ... 9 cm, which should provide a good filling of the die for casting the product-the gearbox housing or the centrifugal pump snail.

2. The need to ensure the strength of polymer concrete in order to withstand the statistical and dynamic loads of the tested products.

The sequence of the researches carried out made it possible to obtain a composite material with the required strength characteristics by simple technology and low cost.

Results and discussion

The conducted research has established the optimal composition of fiber-reinforced concrete, consisting of granite gravel, quartz sand, quartz flour with the addition of steel fiber. Epoxy resin was used as a binder (table 1).

From the investigated composition of fiber-reinforced concrete, the 1st composition with steel fiber was selected, which made it possible to obtain a composite material that fully meets the requirements for the material for the manufacture of centrifugal pump bodies.

For the casting of the centrifugal pump body that meets the necessary requirements, special researches were carried out, which made it possible to work out the technology of manufacturing casting matrices and fiber-reinforced concrete mixtures with the development of casting technology.

Table 1. The investigated compositions of fiber-reinforced concrete.

№	Components	Composition 1		Composition 2		Composition 3	
		Con-sum-ption in %	Con-sum-ption in grams	Con-sum-ption in %	Con-sum-ption in grams	Con-sum-ption in %	Con-sum-ption in grams
1	Granite gravel	51	1000,0	52	1040,0	–	–
2	Rubble	–	–	–		51	1000,0
3	Quartz sand	25,5	502,0	–	–	25,5	502,0
4	Quartz flour	11	220,0	–	–	11	220,0
5	Andesite flour	–	–	33.6	620,0	–	–
6	Fiber:

7	Resin	10,6	200,0	12	240,0	10,6	200,0
8	Hardener	2,0	40,0	2,4	50.0	2,0	10,0

*Note: * - "±" to the total mass*

The technological process of forming elements of centrifugal pump casings consists of the following operations:

• matrix and mold lubrication;
• installation of reinforcing cages;
• laying the fiber-reinforced concrete mixture into a matrix (form);
• molding of body parts;
• removal of finished products;
• drying of finished products.

The carried out analysis found that the most influencing factors on the strength characteristics in the preparation of fiber-reinforced concrete should be considered strict adherence to the technology of preparation of raw materials and the mixing mode of components, as well as the content of fiber. It was found that the dosage of the components of fiber-reinforced concrete should be carried out with an accuracy of ± 2% by weight. This mode of preparation of a fiber-reinforced concrete mixture makes it possible to obtain a homogeneous mixture with an even distribution of all components in its volume. This provides an isotropic solidified mixture with the same characteristics at any point. The analysis of the research results of the factors affecting the strength of fiber-reinforced concrete showed that the optimal time for mixing the components of the mixture for its strength is 5 ... 6 minutes at a working body rotation frequency of 800 ... 1000 rpm.

According to the results of the experiments, it was found that the most rational is the following composition of fiber-reinforced concrete (by volume): granite crushed stone 50 ... 52%, quartz sand 25 ... 26%, quartz flour 11%, steel anchor-type fiber 3-4%, epoxy resin 10-11 %, hardener 2%. Such composition of fiber-reinforced

https://doi.org/10.1051/e3sconf/202128007007

concrete has a density of 2200 ... 2300 kg / m3, compressive strength 230 ... 240 MPa, bending strength 80 ... 100 MPa.

Figure 1 shows the finished body of a standard centrifugal pump 1K 20/30, cast from fiber-reinforced concrete.

Fig. 1. Finished body of a centrifugal pump.

The cast samples and the results of the performed experiments on mechanical tests were presented to the specialists of the quality department and the management group of JSC AZTM for external evaluation of the obtained semi-industrial sample from fiber-reinforced concrete. Experts carried out visual-optical control in order to identify surface defects that could arise during installation and operation.

Visual-optical control was carried out before instrumental and non-destructive control methods. All measurements were made after visual control or simultaneously with it.

During visual-optical control, the following were checked:

- completeness of the pump;
- quality of protective coatings and colors;
- the presence of defects that affect the performance of the pump.

At the same time, special attention was paid to the presence of defects posing a possible danger of subsequent destruction of a part or assembly unit, such as:

- local mechanical damage (tears, kinks, dents);
- stratification of the base material;
- sunsets of the main material;
- deformation of parts and assembly units;
- defects of threads;
- cracks in the base material;

After casting, the halves of the body were glued together with an epoxy compound thickened with adhesive flour, and treated with an abrasive wheel. The glued body in 2 layers is covered with a gelcoat to reduce the roughness of the body surface.

For industrial testing, a 1k20/30 pumping unit with a fiber-reinforced concrete casing is connected to a test bench in the conditions of JSC "AZTM".

The test bench is designed for testing centrifugal pumps. At the test bench, it is possible to conduct research on individual devices used in the automation of a technological process and the following can be determined:

- characteristics of the potentiometric level sensor (LS);
- characteristics of the electromagnetic relay;
- performance characteristics of the centrifugal pump;
- liquid consumption in various ways;
- study the device of the pressure switch and devices for measuring temperature and pressure, determine the thresholds for the pressure switch, measure temperature and pressure.

Evaluation of the effectiveness of the test bench is based on the registration of the parameters of a centrifugal pump in conditions close to production.

Modules of hydraulic and electrical control, which are structurally complete devices, are designed to control, measure the recorded values and monitor the work of the test bench.

Figure 2 shows the hydraulic diagram of the stand. All devices are installed in the body of the hydraulic control module, which are shown on the hydraulic diagram inside a rectangle highlighted by a dash-dot line. These are the following devices:

- CV - check valve;
- PS - pressure switch:
- V1 ... V5 - valves;
- WC - simulator of water consumers;
- T - temperature sensor;
- FM - flow meter;
- MN - manometer.

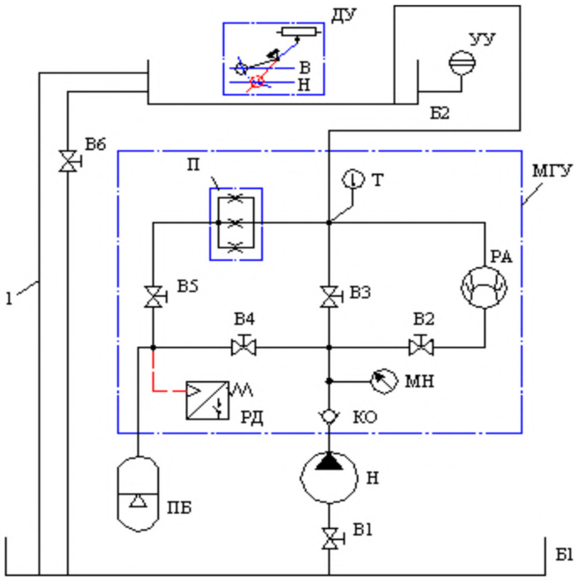

Fig. 2. Hydraulic diagram of the test bench.

In the electrical diagram of the test bench it is indicated (Figure 3):

- lS - potentiometric level sensor (installed in the upper hydraulic tank, pos. 6 in Figure 2);
- EMR - electromagnetic relay;
- PS - pressure switch (installed in the housing of the hydraulic control module);
- DEM - hydraulic pump drive electric motor;
- RH - load resistance;
- A, V, W - ammeter, voltmeter, wattmeter, respectively;
- HL2 - light indication lamp.

The supply voltage of the electrical system is 220 V, alternating current, 50 Hz. Potentiometric level sensor supply voltage - 12 V, constant current.

Comparative tests were carried out on an installation with a fiber-reinforced concrete and a metal casing under identical conditions.

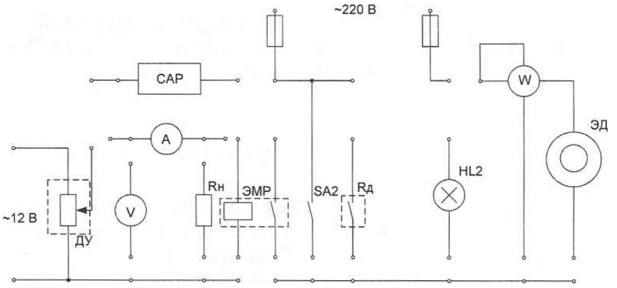

Fig. 3. Electrical diagram of the test bench.

The tests were carried out in the following order:

1. The stand was powered up. For this, the "MAINS" toggle switch on the electrical control module must be set to the upper position. Switch on the pump with toggle switch SA2.

2. Experimental studies were carried out to determine the pump performance. First, acting on the B2 valve, the maximum pressure that the pump develops (according to the MH manometer) was determined. Then, having divided the range of the pump pressure change into 5 intervals, 6 experiments were carried out. In every experiment, the pressure should be constant. The first experiment began with the minimum pump pressure (that is, with the minimum resistance of the network on which the pump was operating).

Each experiment measured:

1. Pressure at the pump outlet $p_н$ (according to the manometer);

2. The time t of passing through the flow meter the volume of water W (the volume W must be set, taking, for example, $W = 0.01$ m^3 (10 dm^3).

3. The power of the N_e supplied to the electric motor (according to the wattmeter) (when determining the power, the readings of the wattmeter were multiplied by 100, then the power was obtained in watts). The measurement results were entered in table 2.

After the completion of the test of the pump with a fiber-reinforced concrete body, the pump with a metal casing was tested in the same way. The measurement results were entered in Table 3.

When processing the research results, the following assumptions were made:

1) the pressure at the pump inlet ($p_в$) is taken equal to the atmospheric pressure (there are two reasons for this assumption: the presence of a liquid back pressure at the pump inlet, since the water level in the lower tank is higher than the pump location level; relatively low pressure losses in the suction pipeline);

2) the vertical coordinates at the pump inlet and outlet are equal, that is, $z_H = z_B$ (the vertical size of the pump is not taken into account);

3) the average fluid flow rates at the pump inlet and outlet are equal to each other, that is, $V_H = V_B$.

Thus, the pump flow is equal to:

$$Q = \frac{W}{t}\,.\ \mathrm{m^3/s} \qquad (1)$$

where, w – volume of water passing through the flow meter, m^3 , t - volume transit time W, s.

Pump power:

$$N = N_{эл} \cdot \eta_{эл}.\ \text{кВт} \qquad (2)$$

where $\eta_{эл}$ – The efficiency of the electric motor (taken constant equal to 0.7).

The pump head was determined by the formula:

$$\mathrm{H} = \frac{P_н}{\rho \cdot g}\,.\ \mathrm{m} \qquad (3)$$

where, $P_н$- pump outlet pressure, MPa, ρ – fluid density, кг/м^3, g – acceleration of gravity

Net pump power:

$$N_п = \mathrm{P}_н \cdot Q.\ \text{кВт} \qquad (4)$$

where, $P_н$- pump outlet pressure, MPa , Q – pump feed, m^3/h

The pump efficiency is:

$$\eta = \frac{N_п}{N}\ .\ \mathrm{kW} \qquad (5)$$

where , $N_П$ – net pump power, kW, N – pump power, kW.

According to the above method, the main parameters of the pump were determined and the results of calculations were entered into tables 2 and 3, and then the operating characteristics of the pump were plotted from the values: $H = f(Q)$, $N = f(Q)$, $\eta = f(Q)$ and comparative characteristics of the pump with fiber-reinforced concrete and metal casing.

Table 2. Test results of a pump with a fiber-reinforced concrete body.

# of experiment	$P_н$ – pump outlet pressure, MPa	W – volume of water passing through the flow meter, m^3	t – volume transit time W, s	$N_{ЭЛ}$ – motor input power, kW	Q – pump feed, m^3/h	N – pump power, kW	H – pump head, m	$N_П$ – net pump power, kW	η – Pump efficiency
1	0,25	0	0	3,0	0	2,1	25,3	1,12	0
2	0,20	0,116	60		6,99		20,2	1,392	62.8
3	0,15	0,158	60		12		15,2	1,422	64.2
4	0,10	0,240	60		13		10,1	1,44	65.1
5	0,05	0,332	60		16		5,1	1,45	45

The results of comparative bench tests of a 1k20 / 30 centrifugal pump with a metal casing and a fiber-reinforced concrete casing are shown in Table 4.

The test results show that the parameters of a pump with a fiber-reinforced concrete body are not inferior in characteristics to a pump with a metal body.

Conclusion

The studies carried out led to the following conclusions:

Table 3. Test results of a pump with a metal body.

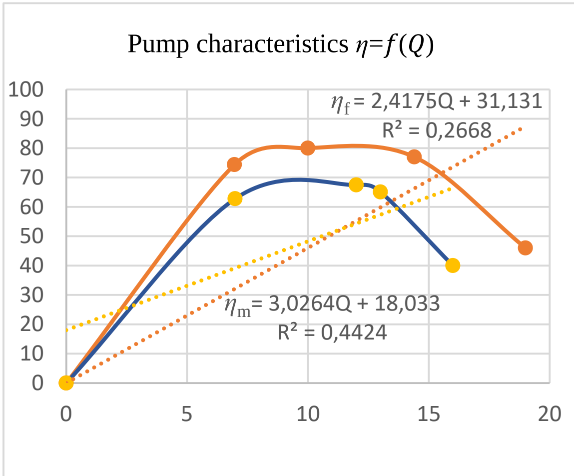

Fig 6. Pump characteristics 1k 20/30: dependence of efficiency on flow η=$f(Q)$

1. Fiber concrete in its characteristics fully meets the requirements for materials for the manufacture of centrifugal pump bodies.
2. The proposed method for the selection of the composition of fiber-concrete mixes allows you to obtain optimal mixes that guarantee the necessary physical and mechanical characteristics.
3. The bodies of centrifugal pumps cast from fiber-reinforced concrete do not require additional machining and have shown good quality during experimental tests.
4. The test results showed that samples made of fiber-reinforced concrete have a strength 30 ... 40% higher than those of metal, which makes it possible to reduce the thickness of the walls of products by 20 ... 25%, which makes it possible to reduce the mass of the pump body by 33-35%.
5. The results of the study showed that when using pump bodies made of fiber-reinforced concrete, the productivity and efficiency of the pump increase by 4-5% due to the smooth inner surface of the casing.

Abstract. Structural schemes of coverings using lightweight roof structure from modern composite materials are investigated in this paper. A comparison of two options for cable-stayed covering of ~~a~~ circus auditorium, one with an orthogonal mesh of cables (according to a standard design) and another one, with a mesh of cables formed by two groups of stabilizing cables are considered. The possibilities of reinforcement with composite material are analyzed. Calculation and preliminary selection of cable-stayed sections are also carried out and presented. The variations of the conditional volume with the relative sag arrows, for varying values of the coefficient q_k have been investigated and shown on graphs. An optimization problem was solved and the optimal result with detailed calculations are proposed and presented in this research which enable the design of the cable-stayed coating with determination of its design characteristics. As a result, the optimum and most economical sections of the cable-stayed covering were obtained. The calculations also show the inexpediency of using a heavy roof structure for saddle cable-stayed coverings due to the exclusion of stabilizing cables from the operation with a large roof weight.

1 The problem and its relationship with engineering tasks

The interest in cable-stayed coverings, which is manifested by many researchers, designers and builders, is common and becoming an actual engineering problem to resolve. This is helped not only by the economic advantages of coatings used, but also by the development of calculation methods and design techniques. Plausible results, associated with the study of static, dynamic and kinematic properties of cable-stayed systems with the use of computer technology, have been achieved. Positive attempts have been made to solve problems of optimal design [1-3].

Currently, scientists are considering issues related to:
– a choice of constructive schemes of a cable-stayed covering;
– study of the stress-strain state of cable-stayed systems;
– methods of solving equations;
– optimal design of cable-stayed systems;
– dynamics of cable-stayed systems;
– construction of cable-stayed coverings;

The relevance of the study is determined by the use of a constructive scheme of coverage, which allows the use of a lightweight roof structure using modern composite materials. The outstanding works of local and foreign scientists in this field over the past 30-40 years are to be commended and encouraging for future research. As a result buildings and structures using cable-stayed systems are quite widespread (coverage of public and industrial long-span buildings, cable-stayed bridges and overpasses) [4, 5].

But there are also problems that hinder the spread of cable-stayed systems in construction. This is, first of all, the lack of regulatory framework for the design and calculation of cable-stayed systems. All parameters and recommendations for design and research can be found only in the works of scientists who are specialized in this field.

2 Analysis of research and publications

Hanging cable-stayed structures are mainly used to cover large-span buildings (structures) of various types [1, 6], such as stadiums, gymnasiums, entertainment and trade buildings, where they are most cost-effective and aesthetically pleasing.

Buildings and structures with cable-stayed (hanging) coating in contrast to the dome and cylindrical coatings, allow to cover the area of buildings (structures) of much larger size without economic losses, while easy to manufacture, install and operate. However, with increasing the area of the cable-stayed cover, respectively, increases the support forces in the cables (flexible threads), which are transmitted to the external support, in which case it is necessary to increase the stiffness parameters of the external support circuit.

Scientists consider issues related to the choice of structural schemes of cable-stayed cover, the study of the stress-strain state of cable systems, methods for solving equations, the optimal design of cable systems, the dynamics of cable-stayed systems, the design of cable-stayed coverings, among others.

Local and foreign experience of building structures using suspension systems are described in the works of Kirsanov, Dmitrieva, Trushcheva, Faibyshenko, Gorev [7-13].

3 Formulation of the problem

The purpose of the study is to analyze the cable-stayed coverings used in long-span public buildings, finding their optimal parameters and choosing an efficient and economical type of roof.

To achieve this, it is necessary to solve the following problems:

– to investigate the state of issues related to the design and calculation of cable systems;

– to find the expedient constructive scheme of a cable-stayed covering, to substantiate its choice;

– to study the construction of the roof of cable-stayed coverings, to develop a new type and to adapt it to the chosen structural scheme.

4 Materials, calculations and results

The problem of designing a cable-stayed cover is considered on the example of a circus building. It is designed on the basis of a typical circus project. The cable-stayed covering covers the auditorium of the circus with a diameter of 48 m.

The design of the cable-stayed cover took place in several stages:

1st Stage. Choice constructive scheme.

2nd Stage. Choice of roof design.

3rd Stage. Calculation and selection of preliminary sections of cables.

1. Choice constructive scheme.

In the typical project the device of a cable covering in the form of a cable-stayed orthogonal grid is provided. The spatial rigidity of the coating is provided by pre-stress followed by monolithic and transformation of the structure into a shell. The surface has the shape of a hyperbolic paraboloid.

Two directions of cables are the minimum necessary for creation of preliminary pressure (thus the outline of a basic contour corresponds to a grid). However, there are cable-stayed nets formed by three or more directions of cables.

A fairly economical roof solution is a light roof, but it requires a high degree of rigidity of the cable-stayed grid. Therefore, a new kinematic structural scheme is proposed, which is a cable-stayed grid with triangular cells.

Cable-stayed mesh with a triangular structure has the advantage that its elementary triangular cell is always flat. This allows the cells between the cables to be filled with fragile materials, such as glass panels or other materials.

A grid with triangular cells can be formed on any surface.

Thus, for a hyperbolic paraboloid, the supporting cables are directed along the line of the main curvature, and the stabilizing ones - at an angle of 45 ° to the main one.

Due to the fact that the existence of right triangles on the surface of a hyperbolic paraboloid is impossible [14, 15], it is assumed that the grid nodes will be arranged by forced fastening.

Fig. 1. depicts a cable-stayed grid offered in a typical design and a cable-stayed grid.

Therefore, the designed structural scheme of covering in the form of a cable grid with two groups of stabilizing cables forming triangular cells is used for implementation.

2. Choice of roof design

The maximum weight of lightweight types of roofs is normally limited to 40-60 kg / m ^{2}.

To achieve the normative indicators of heat transfer resistance, the roof is insulated with foam plates with a density of ρ = 0.5 kN / m^3 and a thermal conductivity coefficient λ = 0.043 W / m ºC.

R_0 – calculated heat transfer resistance m^2·ºC / W:

$$R_0 = \frac{1}{\alpha_в} + R_к + \frac{1}{\alpha_н}, \tag{1}$$

where: $\lambda_в$ – heat transfer coefficient of the inner surface of the fence, W / m ^{2} ºC; $R_к$ – thermal resistance of the enclosing structure, m ^{2}·ºC / W; $\lambda_н$ – heat transfer coefficient (for winter conditions) of the outer surface of the fence, W / m ^{2}·ºC.

The resistance of steel and waterproofing layer is not taken into account. When designing enclosing structures, it is necessary that their heat transfer resistance is not less than the standard value $R_0^н$. According to table 1 [16] $R_0^н$ = 2,6 m^2 ºC /W:

$$R_0 > R_0^н \tag{2}$$

From design requirements 2 plates, 60 mm thick are acceptable. The resistance to heat transfer is determined:

R_0 = 1/8,7 + 0.12/0,043 + 1/23 = 0,1149 + 2,79 + + 0,0435 = 2,917 m^2 ºC / W

R_0 = 2,917м^2· ºC /Вт > $R_0^н$ = 2,6 m^2 ºC / W, and as such, the condition is satisfied.

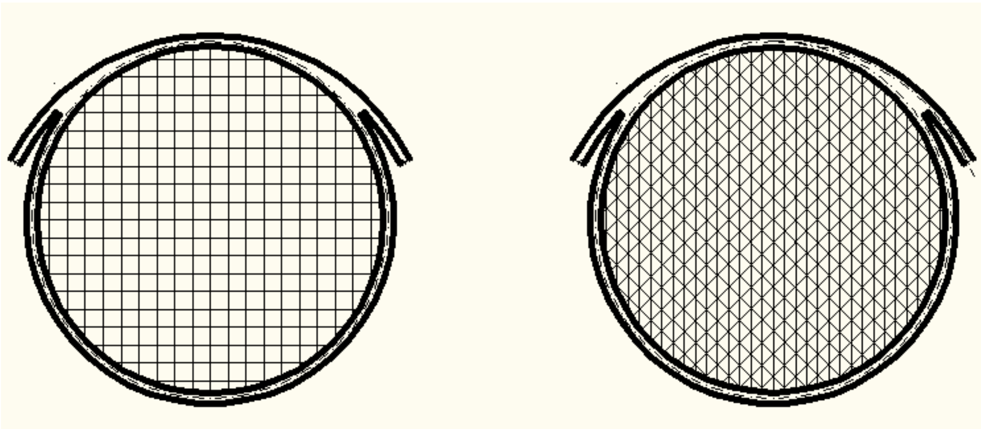
The thickness of the insulation layer is satisfactory.

To fill the triangular cell, a triangular plate of insulation is used, shown in fig. 3 [17]. It is reinforced externally with a composite material.

Let's analyze the possibilities of reinforcement with composite material. Composite materials consisting of a fibrous filler and a binder are suitable for these functions. Such materials are fiberglass and carbon fiber, which are widely used in construction.

Comparison of these materials:

1. Fiberglass – a plastic material consisting of fiberglass filler and binders (thermoactive and thermoplastic polymers). This is a material with a low specific weight and specified characteristics. They have low thermal conductivity, high strength, biological and atmospheric resistance.



a) ***b)***

Fig. 1. Cable-stayed cover of the circus auditorium: *a* – with an orthogonal cable-stayed grid (according to a typical project); *b* – with a cable-stayed grid formed by two groups of stabilizing cables.

Fig. 2. Roof construction: 1 – waterproofing layer; 2 – metal membrane; 3 – vapor barrier; 4 – insulation.

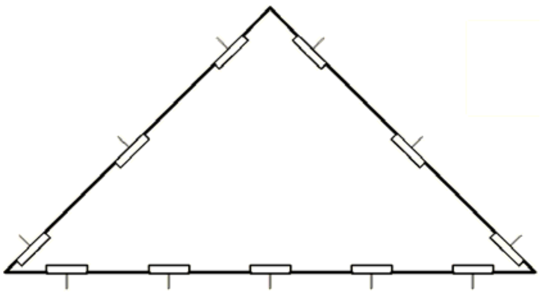


Fig. 3. The scheme of a triangular plate of a heater.

2. Carbon fiber – a material of interwoven threads of carbon fiber, located in a matrix of polymer resins. This material also has low weight and high strength (dominated by specific characteristics of steel). They are also resistant to external influences.

Comparative characteristics of these materials are considered in table. 1.

As seen from the table, fiberglass and carbon fiber have approximately the same strength characteristics with a lower modulus of elasticity of fiberglass relative to carbon fiber, but the cost of fiberglass is 9-10 times lower. Therefore, it is more appropriate to use fiberglass for external reinforcement.

Reinforcement is performed as follows: two triangular plates of polyfoam are placed on top of each other and fiberglass membrane is laid between them, which is fixed at the edges of metal plates with a thickness of 3 mm, which are fastened together with a bolted connection. This structure is externally reinforced with rolled fiberglass. Fastening of plates among themselves occurs by means of metal welded details of channel section. There are metal hooks which fastens the plate to the cables (fig. 4).

Table 1. Comparative characteristics of reinforcement materials.

Characteristic	**Fiberglass**	**CFRP** (carbon fiber)
Density, kg / m^3	1800 – 1900	1700 – 2000
Modulus of elasticity, GPa	70	140 – 145
Tensile strength (tensile), MPa	1700	800 – 1100
Poisson's ratio	0,2 – 0,25	0,25 – 0,3
Thermal conductivity, W / m ºC	0,75	0,5 – 0,1
Coefficient of linear expansion, 10^{-6}	0,45 – 8,3	0,8 – 5,2
Resistance to aggressive environments	Resistant	Resistant
Price, UAH / m^2	10 – 14	110 – 130

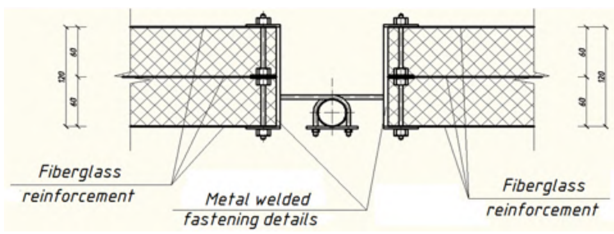

Fig. 4. Knot of fastening of plates to cables.

Fiberglass is additionally glued to metal and foam with CERESIT CT83 polymer-cement adhesive, which works effectively to allow deformation. The joints between the plates are filled with elastic mounting foam, which is resistant to extreme mechanical displacement.

3. Calculation and preliminary selection of sections

The following calculation is suitable for technical and economic comparison.

Output data:

The cover of the circus auditorium is round in plan, 48 m in diameter, covered by a cross system of cables, consisting of one group of load-bearing cables and two groups of stabilizers. According to standards [18], the snow load is 1.0 kPa, the wind load is 0.88 (taking into account all coefficients). As bearing elements of a grid we accept ropes of double twisting like LK-RO of a design 6 x 19 x (1 + 6 + 6/6 + 14) +7 x 7 x (1 + 6) as per prevailing standards [19] with the coefficient $k_p = 0.81\ldots 0.85$ and the temporary resistance of the break wires – 1,764 GPa.

The load on the coating will be entered in table. 2. Thus wind and snow loading is simply considered to be evenly distributed on a covering surface.

In saddle-shaped coverings (with a surface in the form of a hyperbolic paraboloid) the struts of all bearing ropes will be the same due to the uniform load on the cover and the pressure of the stabilizing ropes on the bearing. As such, we can distinguish one carrier thread, which does not differ in work from others, and one stabilizing thread, which characterizes the same pressures of all stabilizing cables on the carriers.

In design practice, the magnitude of the prestressing system (the magnitude of the forces of interaction of the cables) is often set, provided that the stabilizing cables are almost excluded from operation at full load on the coating. In this case, the share of interaction forces in the total load on the carrier thread is small and the determination of the forces in the grid, carried out by this method of calculation, is accurate enough to assign cross-sections of threads in advance.

Therefore, the forces in the bearing and stabilizing threads are determined by the formulas:

$$T_{\text{н}} = \frac{d_{\text{н}} \cdot l^2 \cdot a}{8 \cdot f_{\text{н}}} \cdot \left[g_1 + q + p_1 \cdot \left(\frac{l_c^2}{C \cdot l_{\text{н}}^2 + l_c^2} \right) \right] \qquad (3)$$

$$T_{\text{н}} = \frac{d_c \cdot l^2 \cdot a}{8 \cdot f_c} \cdot \left[q - g + p_w \cdot \left(\frac{C \cdot l_{\text{н}}^2}{C \cdot l_{\text{н}}^2 + l_c^2} \right) \right] \qquad (4)$$

where: d – the steps of the respective cables in the grid (since the stabilizing cables are located at an angle of 45° to the carriers, then $d = d_c = d_{\text{н}} \cdot \sqrt{2}$); $l_{\text{н}}$ and l_c – corresponding spans of the supporting and stabilizing cable; $f_{\text{н}}$ and f_c – corresponding sagging arrows; g_1 – part of the constant load (own weight of load-bearing structures and connections) applied to the pre-stress (0.13 kPa); q required value pre-stressing; p_1 – temporary (snow) load plus part of the constant load g_2 (1,4 + 0,57 = 1,97 kPa), that is applied after pre-stressing ($g_2 = g - g_1$); g – constant load (0.7 kPa); p_W – wind load (1.22 kPa); C – the coefficient of interaction of groups of cables; $a = \sqrt{1 + 16/n^2}$, where: $n = l/f$ – the ratio of the span to the sagging arrow; $q = [(p_1 \cdot C)/(C+1)] + \Delta q$, where Δq – additional part of the pre - voltage of the system (it is recommended to take $\Delta q = 0{,}1 \ldots 0{,}3 \cdot q$;

$$C = \frac{\mu_{\text{н}}^2}{\mu_c^2} \cdot \frac{A_{\text{н}} \cdot E_{\text{н}} \cdot f_c^2}{A_c \cdot E_c \cdot f_{\text{н}}^2} \qquad (5)$$

where: $\mu_{\text{н}}$ and μ_c – appropriate cable extensions $\mu = L/l$; L – design length of flexible thread; $A_{\text{н}}$ and A_c – the corresponding cross-sectional areas of the cables; $E_{\text{н}}$ and E_c – corresponding modulus of elasticity of cables; $\mu = 1 + \frac{8 \cdot f_{\text{н}}^2}{3 \cdot l^2} + \frac{tg^2\alpha}{2}$, where α – the angle of inclination to the horizontal of the line connecting the supports (fig. 5)

Table 2. Coating load.

Load	**Normative value, kPa**	**Coefficient of reliability on loading**	**Estimated value, kPa**
– own weight of a cable-stayed grid (preliminary)	0,12	1,1	0,13
– waterproofing two-layer rolled carpet of waterproofing			
– steel membrane	0,08	1,3	0,1
t = 1 mm;			
ρ = 7800 kg / m^3	0,08	1,1	0,09
– plates of a heater			
t = 120 mm,			
ρ = 0.050 kg / m^3	0,06	1,3	0,08
– false ceiling	0,25	1,2	0,3
Total:	0,59	6	0,7
Wind load	0,88	1,4	1,23
Snow load	1,0	1,4	1,4

As such, for round - in terms of cable-stayed grids from identical cables: $l_{\text{н}} = l_c$, and $E_{\text{н}} = E_c$.

Necessary cross-sections of ropes are found by the formulas:

$$A_{\text{н}} = \frac{1{,}6 \cdot T_{\text{н}}}{k_p \cdot R_{un}} \qquad A_c = \frac{1{,}6 \cdot T_c}{k_p \cdot R_{un}} \qquad (6)$$

where: R_{un} – temporary resistance of the wire to rupture.

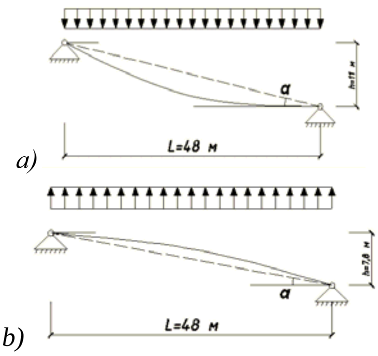

Fig. 5. Calculation schemes of cables: *a* - carrier, *b* - stabilizing.

As can be seen from the above formulas, the cross-sectional area of the ropes depends on several factors:

1. arrows sagging ropes;
2. the magnitude of the pre-stress;
3. the coefficient of interaction of groups of cables;
4. the step of the cables in the grid, which also

indirectly affects each other.

Therefore, to find the cross sections of the ropes (they should be the smallest) it is necessary to solve the optimization problem. As a target function, we use the relative volume of metal in the cables:

$$F = \sum L_н \cdot A_н + \sum L_c \cdot A_c \to \min \qquad (7)$$

where the sum of the lengths of the cables is as follows:

$$\sum L_н = \mu_н \cdot \left(2 \cdot \sum\nolimits_2^n l_{нi} + l_н\right) \qquad (8)$$

$$\sum L_c = \mu_c \cdot \left(2 \cdot \sum\nolimits_2^b l_{cj} + l_c\right) \qquad (9)$$

where: $n = R/d_н$ and $m = R/d_c$; R – coverage radius in the plan. Formulas (8) and (9) can be rewritten as:

$$\sum L_н = \mu_н \cdot \frac{S_{coating}}{d} \qquad (10)$$

$$\sum L_c = 2 \cdot \mu_c \cdot \frac{S_{coating}}{d \cdot \sqrt{2}} \qquad (11)$$

$S_{coating} = \pi \cdot 24^2 = 1809$ м^2.

Let's set the limits of variables:

1) Instead of sagging arrows, relative sagging arrows are used: $D_н = f_н/l_н$, та $D_c = f_c/l_c$. According to the recommendations [25], they vary within: $D_н = 1/15 \ldots 1/8$, $D_c = 1/25 \ldots 1/10$.

2) The magnitude of the pre-stress will be characterized by a coefficient $q_k = (q + \Delta q)/q$, which varies within 1,1…1,3.

3) The coefficient of interaction of groups of cables will depend on the coefficient $B = A_s / A_n$, which is recommended to take 0.3… 0.5 [25].

Taking into account all the formulas, certain dependencies and initial data, we finally have:

Target function:

$$F = \mu_н \cdot \frac{1809}{d} \cdot A_н + 2 \cdot \mu_c \cdot \frac{1809}{d \cdot \sqrt{2}} \cdot A_c$$

where: $A_н = T_н \cdot 11{,}8 \cdot 10^{-9}$; $A_c = T_c \cdot 11{,}8 \cdot 10^{-9}$;

$$T_н = \frac{d \cdot 6 \cdot a}{D_н} \cdot \left[0{,}13 + q + 1{,}97 \cdot \left(\frac{1}{C+1}\right)\right];$$

$$T_c = \frac{d \cdot \sqrt{2} \cdot 6 \cdot a}{D_c} \cdot \left[q - 0{,}7 + 1{,}22 \cdot \left(\frac{1}{C+1}\right)\right];$$

$$q = \frac{1{,}97 \cdot C}{C+1} \cdot k_q; \qquad C = \frac{\mu_н^2}{\mu_c^2} \cdot \frac{D_c^2}{D_н^2} \cdot B;$$

$$a_н = \sqrt{1 + 16 \cdot D_н}; \qquad a_c = \sqrt{1 + 16 \cdot D_c};$$

$$\mu_н = 1{,}053 + \frac{8 \cdot D_н}{3}; \qquad \mu_c = 1{,}026 + \frac{8 \cdot D_c}{3};$$

Limitation:

– $D_н = 1/15 \ldots 1/8$, $D_c = 1/25 \ldots 1/10$;

– $q_k = 1{,}1 \ldots 1{,}3$;

– $B = 0{,}3 \ldots 0{,}5$.

It can be seen that the target function does not depend on the pitch of the cables in the grid. Therefore, we assign it from the design requirements: the largest side of the triangular cell is taken as 3 m, hence d = 1.5 m.

There is also another requirement - the deformability of the coating which is as follows:

$$\Delta f = \frac{3}{128} \cdot \frac{\mu_н^2}{f_н^2} \cdot \frac{p \cdot l^4}{E \cdot A_н} \le \frac{l}{200} \qquad (12)$$

where: p – snow load.

The solution of the optimization problem is performed in Microsoft Excel, with the help of the "Search solution" function.

The results are presented in tables 3 and 4.

Table 3. Initial data.

Coverage radius in the plan, m	24
load:	
permanent:	0,7
– to voltage, kPa	0,13
– after stress, kPa	0,57
Temporary (snow), kPa	1,4
Wind, kPa	1,22
Temporary resistance of a wire of a rupture, GPa	1,764
Coefficient of working conditions	0,81
Modulus of elasticity of ropes, GPa	160

According to the obtained values of the cross-sectional area, we select ropes by assortment.

Thus the ropes of the bearing group – Ø33 mm with $A_н$ = 4,977 cm^2, the stabilizing group – 2 ropes Ø 12,5 mm with A_c = 1.4182 cm^2

Deformability of the coating 0,03 < 48/200 = 0.24. All conditions are met and the optimum solution is found.

To connect the cables to each other, a metal plate is used, to which the cables are fastened with a bolted connection (Fig. 6, 7). Fastening of cables in knot is compulsory.

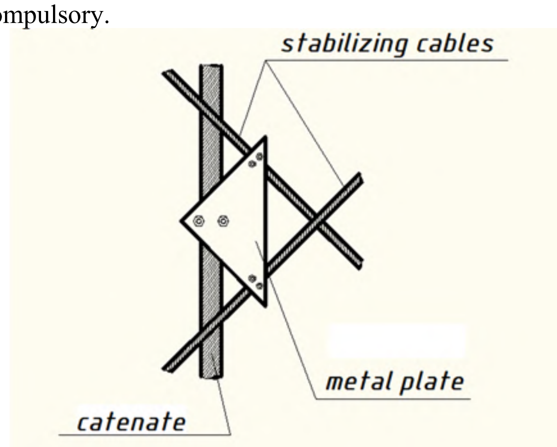

Fig. 6. Knot of fastening of cables among themselves.

Reinforced concrete support ring is designed prefabricated monolithic type. The reference circuit is partially prefabricated.

The cables are attached to the embedded parts on the side elements by means of a wedge-sleeve anchor. After adjusting the position of the cables, the contour is added to the design dimensions.

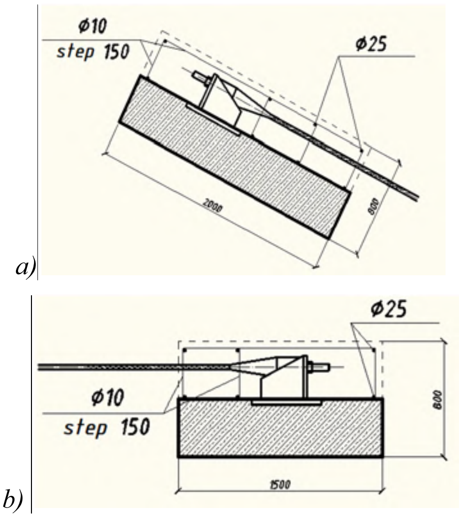

Fig. 7. Knots of adjoining of cables to a basic reinforced concrete ring: *a* – adjoining to the top onboard element, *b* – adjoining to the lower onboard element.

– stabilizing		1,612	

Fig. 8 shows the curves of the conditional volume of the cables for different values of the relative sagging arrows of the stabilizing and supporting cables, at different values of the coefficient q_k. The graphs show that the most economical are the options with $q_k = 1.3$ and with larger values of the sagging arrows of the supporting cables.

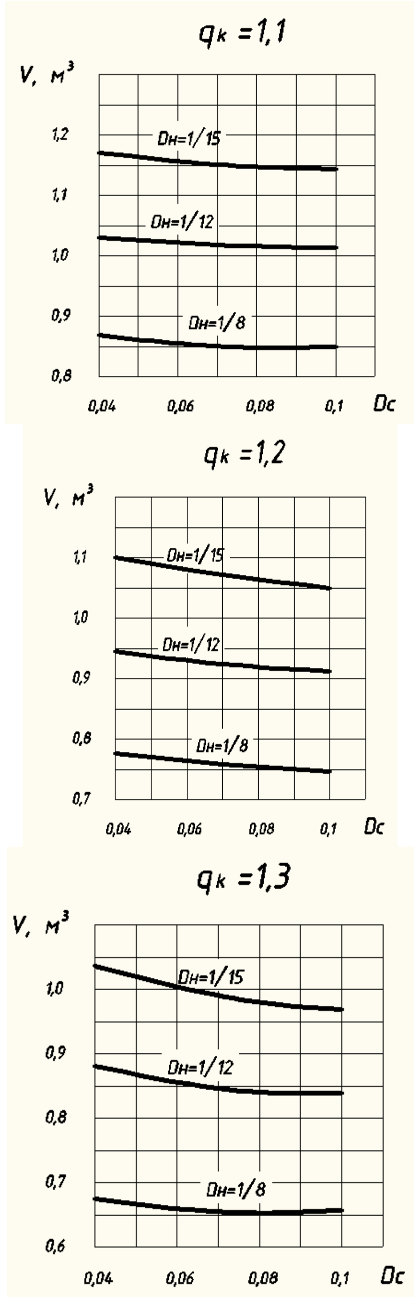

Fig. 8. Variation of the conditional volume with the relative sagging arrows, at values of the coefficient q_k.

The next step is to perform the same operation for a typical option – orthogonal mesh.

Calculations are performed according to the same formulas, but taking into account that the step in the grid is the same, that is, 2,4 m.

The load on the coating will be entered in table 5.

The solution of the optimization problem is entered in tables 6 and 7.

As can be seen from the table, this problem has no solution, as the force in the stabilizing cable is close to zero. This is due to the fact that the coating is stabilized due to its own weight, and therefore the stabilizing cables are almost not included in the functioning of the structure.

By assortment we find the necessary ropes. Ropes of the bearing group – 2Ø36 mm with $A_н$ = 11,7962 sm², stabilizing ropes are assigned the same from the design conditions.

Table 5. Load on the coating.

Load	Normative value, kPa	Coefficient of reliability on loading	Estimated value, kPa
– own weight of a cable grid (preliminary)	0,12	1,1	0,13
– waterproofing two-layer rolled carpet of waterproofing	0,08	1,3	0,1
– asphalt screed t = 15 mm; ρ = 1800 kg / m^3	0,27	1,3	0,46
– metal membrane t = 1 mm	0,08	1,1	0,09
– plates of a heater t = 60 mm, ρ = 0.050 kg / m^3	0,03	1,3	0,05
– reinforced concrete slabs t_{priv} = 53 mm ρ = 2500 kg / m^3	1,54	1,1	1,7
– filling of seams	0,2	1,1	0,7
– false ceiling	0,25	1,2	0,3
Total:	2,57	9,5	3,75
Wind load	0,88	1,4	1,23
Snow load	1,0	1,4	1,4

Table 6. Initial data.

Coverage radius in the plan, m	24
load:	
permanent:	2,96
– to voltage, kPa	0,13
– after stress, kPa	2,83
Temporary (snow), kPa	1,4
Wind, kPa	1,22
Temporary resistance of a wire of a rupture, GPa	1,764
Coefficient of working conditions	0,81
Modulus of elasticity of ropes, GPa	160

It is possible to investigate the dependence of the degree of operation of the stabilizing cables on the load on the coating. In fig. 9 and 10 show graphs illustrating this phenomenon.

The graphs show that the most effective stabilizing cable works at a load of 0.5-1.2 kPa, at a load of 2.6-3.0 kPa it becomes ineffective, and at lower values also begins to perform the functions of the supporting cable. From which it can be concluded that the most rational type of roof for saddle-shaped cable-stayed structures is a light roof.

According to the design organizations and the analysis of the indicators of the constructed buildings, the relative cost of cable coverings is:

– 56-60% of the cost of prefabricated reinforced concrete shell;

– 40-44% of the cost of coating on steel arches;

– 35-39% of the cost of the lattice steel coating.

Table 7. Solution of the optimization problem.

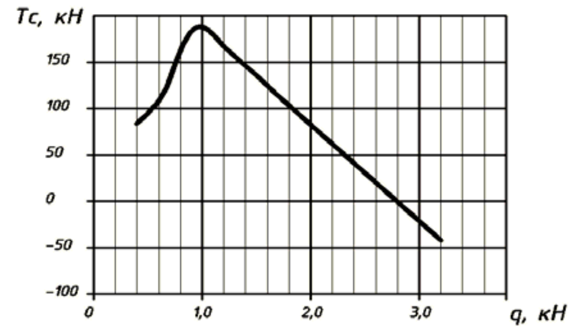

Fig. 9. The dependence of the tension of the stabilizing cable on the load on the coating

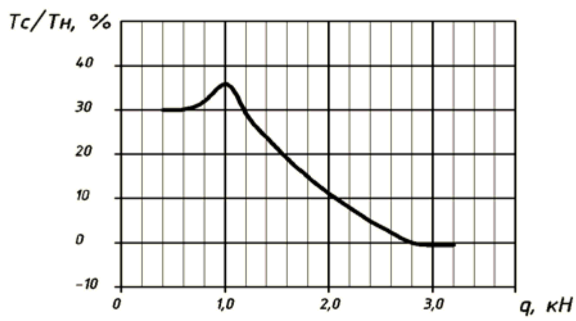

Fig. 10. Dependence of relative tension of stabilizing cables (%) on loading.

In fig. 11 shows the average relative costs of steel and concrete for different types of coatings.

Fig. 12 and 13 show the costs of steel and concrete for different roofing systems of public buildings.

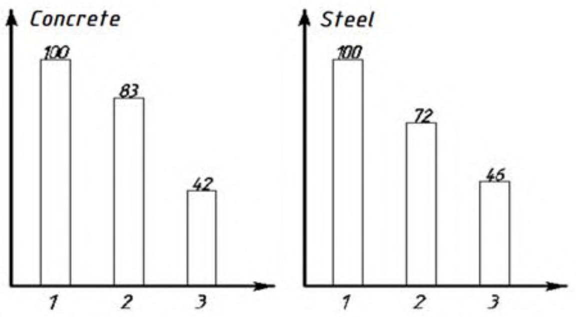

Fig. 11. Relative costs of concrete and steel for: 1 – coating of typical beam elements; 2 – covering from prefabricated reinforced concrete vaults-shells; 3 – cable-stayed cover.

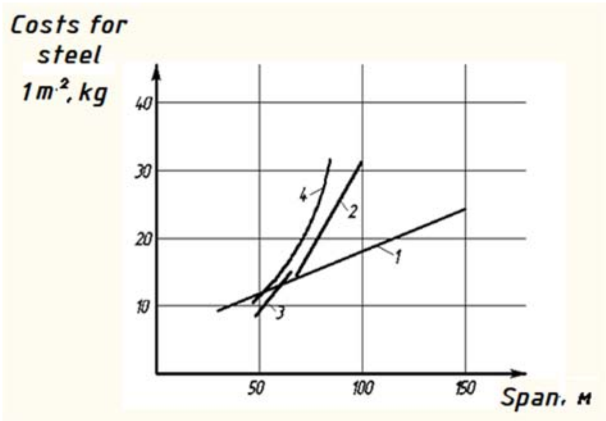

Fig. 12. Costs of steel per m^2 of coating for: 1 – cable coating; 2 – reinforced concrete shells; 3 – beam reinforced concrete structures; 4 – coating on steel trusses.

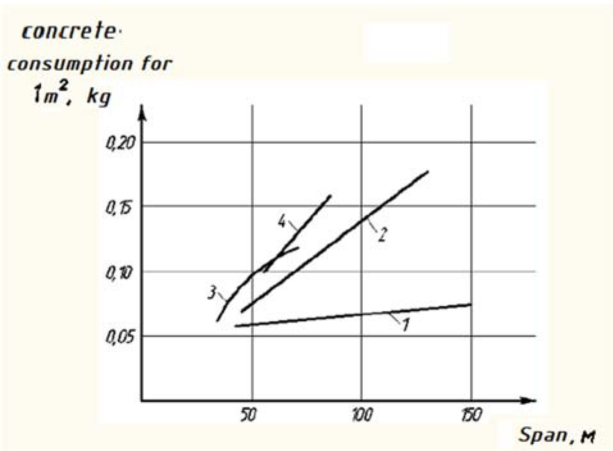

Fig. 13. The cost of concrete per m^2 of coating for: 1 – cable cover; 2 – reinforced concrete shells; 3 – beam reinforced concrete structures; 4 – coating with reinforced concrete slabs.

Finally, from the above characteristics, it can be seen that the cable cover is a more economical type of coating, especially with large spans.

5 Conclusions

Cable-stayed structures are more economical compared to other types of roofs, but their widespread use today is complicated by the lack of design and calculation standards, as well as design solutions dated 30-40 years ago.

The constructive scheme of a cable-stayed covering formed by two groups of stabilizing cables is presented and it is shown that an elementary triangular cell is formed, which allows the use of fragile roofing materials.

A new type of coating plate is proposed, consisting of triangular plates of fiberglass-reinforced insulation. This makes it possible to facilitate the design of the coating without reducing the strength characteristics.

An optimization problem was solved to design the cable-stayed cover and determine its characteristics. As a result, the optimal cross-sections of the cables were obtained. For comparison, the optimization problem for a typical coating variant was also solved.

The calculation shows the inexpediency of using a heavy roof structure for saddle-shaped cable-stayed coverings due to the exclusion from the work of stabilizing cables with a large weight of the roof.

The developed design of a cable covering is more economical in comparison with a typical design of a roof, with reduced materials and more effective performance of the elements.

Abstract. The analysis of the process of thermal modification of wood, which was modified by a controlled process of pyrolysis of wood heating (> 180 ° C) in the absence of oxygen, which causes some chemical changes in the chemical structures of cell wall components (lignin, cellulose and hemicellulose), durability. It is proved that in the process of thermal modification the decomposition of hemicelluloses and the amorphous part of cellulose occurs, and therefore the amount of substances that are the environment for the development of fungi in wood significantly decreases. In addition, lignin and the formed pseudolignin undergo a process of polymerization and redistribution of cell volume and give cell walls greater density, hardness, increase hydrophobicity (water repellency), thereby reducing their ability to absorb moisture and edema. Polymerized lignin fills the inner cavity of the cell, forming a closed porous structure with a low ability to bind water. It was found that the most effective parameter for reducing such substances is the temperature and exposure time. The results of thermogravimetric researches are given, the dependence of weight loss on temperature of researches on the basis of which activation energy is calculated is defined. The results of determining the activation energy show that for hardwood species this value exceeds more than 1.5 times compared to softwood.

1 Introduction

Wood, as a building material, is widely used in construction and architecture due to its mechanical and operational properties. But under the influence of atmospheric factors it is destroyed. Due to the fact that these materials are sensitive to moisture and biological damage, ie the ability to maintain functional properties under operating conditions. It is possible to increase the level of operation of facilities that use building structures made of wood. The essence of the method is to give the wood the ability to resist moisture, the spread of biodamage, which contributes to the destruction of wood and accelerate the destruction process.

Given the above, the modification of wood difficulties for the application of technological modes like time, temperature. This is primarily due to the fact that the structure and composition of wood are different and the modification process is not achieved, and the use of thermodified wood leads to its destruction [1].

Knowledge of physical and chemical properties of substances such indicators of quality, the mechanism of action of the materials allows you to make their choice on the basis of economic performance, duration and application security, environmental aspects, etc. [2, 3]. And the application allows protection to maintain their function when operating within a specified period of time [4-6].

Therefore, the development of technological modes for wood modification, research in thermophysics, the influence of structural features, this process is an unresolved component of ensuring the stability of building structures made of wood. So it is necessitate the establishment of a thermal modification mechanism for such materials.

2 Analysis of recent research and publications

In recent years towards research on thermal modification of wood known work aimed at studying the equilibrium moisture during modification, dimensional stability, durability and mechanical properties of modified wood [7]. Loss of weight, wettability, color, wood and chemical transformations subsequently been widely studied. While the necessary works that focus on quality control, modeling and study of the causes of improved properties of the modified wood.

Thermomodified wood is one of the best materials for lining [8]. In this regard measured the moisture thermally modified heat and low moisture content of thermally modified wood in comparison with the standard spruce. But it is not specified what was the degree and modes of wood modification.

Increased use of thermally modified wood [9] led to the need for reliable quality control, including control of products deviations within certain limits, allowing you to control third party in the event of certification and regulation of the complaints and demands of consumers. However, it is not specified what methods are needed to

characterize the change in quality in terms of improved target properties of modified wood during industrial production.

A study of changes in swelling and surface roughness of wood alder and elm normal after heat treatment at two different temperatures and duration [10]. Established that the parameters of swelling and surface roughness vary considerably for the two two-temperature heat treatment durations. The value of swelling and surface roughness decreased with increasing treatment temperature and time of treatment, but these technological parameters.

The characteristics of wood due to weather conditions change over time, especially the color, which reflects chemical changes [11]. An assessment of the change in color and reflectivity of wooden surfaces due to artificial weathering, obtained using a solar box chamber that simulates external conditions and subsequent leaching of water. As the weathering time increases, the untreated surfaces of the wood samples darken. While the modified samples lighten to have a similar color or, in any case, to reduce the chromatic difference that was at the beginning of the weathering tests.

During the heat treatment is many chemical reactions that lead to changes in the components of the primary cell walls of wood and darkening material. Among other changes, thermodified wood is more resistant to fungal decay and more stable at times than untreated. This make it suitable for use indoors and outdoors as cladding, flooring, floors, garden furniture and window frames [12].

Laboratory tests have shown the positive impact of thermal modification durability, dimensional stability and thermal conductivity of wood [13]. The monitoring results showed that the elements and windows of thermally modified spruce have a significantly lower moisture content in the wood compared to the windows of unmodified, and that the wax also has a positive effect on humidity.

Natural aging is usually a relatively slow process because the artificial aging plays a role important in assessing the results by reducing the time compared to the natural weathering conditions. The approach is to protect the surface with various types of commercial products such as water-based solvents with a high solids content, powder coatings and substance-free products [14].

One approach is the modification of wood, a set of processes that provide the treated material over the ability to cope with the damage caused by the environment, by increasing the duration of treatment. The process is also performed to enhance the physical, mechanical or aesthetic properties of wood and derived products with the advantage that is not harmful to users and the environment, as well as natural wood [15].

Several authors reported an increased resistance to decay for different wood species and several types of rots. The important degradation of hemicelluloses due to thermal treatment, which are generally considered as an important nutritive source as well as a prime key in the hygroscopic wood behavior for the development of wood rotting fungi. Modification of lignin network are also be involved to explain the ineffectiveness of fungal enzymatic attacks. These heat treated wood modifications are represented by mass loss (ML). Various authors compared the weight loss (WL) caused by fungal attack to the decrease in mass of wood by heat treatment (ML).

Wood heating will lead to different processes that always depend on the heating mode used. It is recognized that hemicelluloses are degraded to a greater extent than other macromolecular components, but the relative stability of cellulose and lignin is much more difficult to determine. As is not the case above, when the wood is heated, heat-labile wood polymeric components (hemicelluloses) begin to decompose, resulting in the production of methanol, acid, and various volatile heterocyclic compounds (furans, etc.). In general, the loss of polysaccharide material becomes particularly important at temperatures above 180 °C, which largely depends on the processing conditions. However, changes in the degree of polymerization may appear at lower temperatures (above approx. 150 °C), depending on the heat treatment conditions. The total polyoses (hemicelluloses) containing a large proportion of xylan are oxidized more slowly and consume less oxygen than pure xylan. According to some studies, the decomposition of hardwood xylan begins at a temperature close to 200 °C in a normal atmosphere. Even though lignin is considered to be the thermally most stable component of wood, various changes have been observed even at temperatures below 200 °C. Assessment of lignin content in thermally treated woods indicated the increase of non-hydrolyzable residue with increasing temperature up to 200 °C [16].

There are a number of thermal modification methods that can be applied to wood, and the exact method of treatment can have a significant effect on the properties of the thermally modified wood. Major process variables are the following: time and temperature of treatment, treatment atmosphere, pressure, closed vs. open systems, wood species, wet and dry systems, sample dimensions, and use of catalysts. Also, under certain conditions, changes in wood can be observed even at 100 °C [17].

Thermally modified wood has been produced for more than 20 years, mostly in Finland and other countries of Western Europe. It is made of non-durable and less-durable wood species, such as beech, birch, pine, and spruce, etc. ThermoWood® is produced by a heat treatment process in the presence of steam and is therefore typical hygrothermal treatment. The steam acts as a blanket to reduce the oxidative degradation of wood and there are also further reactions that occur due to the presence of moisture. Because of the presence of steam, the air content in the kiln is limited from 3 to 5% during the heat treatment process [18].

Thus, from the literature it is established that thermal modification of wood is able to withstand destruction. All this gives grounds to assert that it is expedient to conduct a study to determine the parameters that provide resistance to destruction, as well as influencing the mechanism of action in the protection of wood. Therefore, thermal analysis of wood, the influence of temperature and time on this process is an unresolved component of ensuring the stability of building structures made of wood, which necessitated research in this area.

The purpose of this work is to study the activation energy of decomposition of wood and installation efficiency at thermal modification.

3 Raw materials and methods

To establish the mechanism of thermal modification of wood chips used samples of the wood as hornbeam, ash, pine. The weight of the sample was 190 mg.

Thermogravimetric study of thermal degradation processes in dynamic mode using derivatograph Q-1500 D, heating rate – 2.5 degrees per minute, a sample comparison - powder α-corundum material crucibles - alund sensitivity galvanometers, DTA – 250 mkV, DTG – 500 mkV.

4 Results and discussion

Direct data on the processes occurring in the samples of materials during their heating in the dynamic mode were obtained as a result of thermogravimetric studies. The results of the analysis of the studied materials are illustrated (Fig. 1, Table 1).

In the studied wood sample at temperatures from 75 to 100 ºC, endothermic processes take place, which are accompanied by a loss of up to 6% of their mass. Such processes are caused by the evaporation of chemically unbound water without destruction of the sample material. In addition, organic matter loses constitutional water (endoeffect with a maximum of 150 °C with additional weight loss). In the temperature range 180-250 ºC, the temperature range often used for heat treatment, wood undergoes important chemical transformation. And at temperatures above 250 ºC begins carbonization processes with the formation of CO^2 and other pyrolysis products [19, 20].

Hemicelluloses are the first structural compounds to undergo thermal action, even at low temperatures (about 140 °C). It should be noted that the basis of nutrition of biological pests of wood is hemicellulose and the amorphous part of cellulose, and the defeat of wood by different types of fungi and mold is possible only at high humidity. Because hemicelluloses are hygroscopic and intensively absorb and bind moisture, hemicelluloses create favorable conditions for the development of fungi and mold on wood. The decomposition of hemicellulose begins with deacetylation, and acetic acid is released, which acts as a catalyst for depolymerization, which further increases the decomposition of the polysaccharide. In addition, lignin and the formed pseudolignin undergo repolymerization and redistribution in cell volume. They give the cell walls greater density, hardness, increase hydrophobicity (water repellency), thereby reducing their ability to absorb moisture and swell. Repolymerized lignin fills the inner cavity of the cell - forming a closed-porous structure with a low ability to bind water. For Scots pine, which is treated at temperatures from 205 °C to 230 °C for 4-8 hours, the lignin content increases from 24.5% to 38.7%, respectively, and the hemicellulose content decreases [21].

The temperature at which the intensive destruction of wood begins, ie there is a rapid loss of mass of the samples, is 215-250 °C. In particular, exothermic oxidation processes take place in a wood sample along with endothermic pyrolysis processes (cleavage of volatile products) even at relatively low temperatures. The main increase in weight loss in the temperature range of 180-220ºC occurred due to the extractives of water and ethanol as a result of polysaccharide degradation. During heat treatment, the formation of liquid and gaseous phases in addition to solid wood. The liquid phase at temperatures of 200-250 °C is almost exclusively water and acetic acid with small amounts of formic acid, furfural and methanol [22]. Acids catalyze the decomposition of polysaccharides and reduce their content (Table 1).

Thus, the thermogravimetric parameters enable to determine the rate of thermal decomposition of the material at a given temperature and therefore show a qualitative assessment of the effects of heat, but more important task is to determine the activation energy thermooxidative degradation.

Table 1. The results of research on wood samples.

Pine wood						
Mass loss (%) for temperatures						
76°C	140°C	150°C	160°C	190°C	200°C	220ºC
1,5	2,1	3,2	4,1	5,3	6,0	6,5
Hornbeam wood						
Mass loss (%) for temperatures						
76°C	140°C	150°C	160°C	190°C	200°C	220ºC
1,2	1,3	2,6	3,7	4,4	5,8	6,2
Ash wood						
Mass loss (%) for temperatures						
76°C	140°C	150°C	160°C	190°C	200°C	220ºC
1,3	1,4	2,8	4,2	4,9	6,1	6,4

Calculation of kinetic parameters TG curve, which satisfactorily describes the kinetics of decomposition of solids based on the equation [22-23]:

$$-\frac{\mathrm{dm}}{\mathrm{dt}} = \mathrm{k} \cdot \mathrm{m}^{\mathrm{n}}, \qquad (1)$$

where is the

m – the mass of the sample that entered the decomposition reaction, mg;

n – reaction order;

k – specific reaction rate of decomposition of the material.

The dependence of the specific decomposition rate of the material on temperature is described by the Arrhenius equation:

$$\mathrm{k} = \mathrm{A} \cdot e(-\mathrm{E}/\mathrm{RT}), \qquad (2)$$

where is the

A – preexponential multiplier;

e – activation energy, kJ / mol;

R – universal gas rack, 8,314 kJ / (mol·K).

For separate stages of destruction, a possible method of calculating the activation energy is the method described in [23], which shows that the parameter E, under other equivalent conditions, is a measure of resistance to thermal oxidative destruction of the material.

The following decomposition scheme is typical for wood:

$$A_{(\text{тв})} \rightarrow B_{(\text{тв})} + C_{(\text{газ})} \qquad (3)$$

and determining the speed of decomposition reaction enables the equation:

$$-\frac{dm}{dT} = \frac{A}{V_{\text{нагр}}} \cdot e^{-E/RT} \cdot m^{n}. \qquad (4)$$

The calculation of E and n is based on the mathematical processing of the TG curve using the dependence [15]:

$$\ln\left(\ln\frac{100}{100-\Delta m}\right) = -\frac{E}{R}\cdot\frac{1}{T}. \qquad (5)$$

In this equation Δm – mass loss (%) at each temperature in the range of decomposition of the material, which is the process of the first order (n = 1) and provided depending linearization:

$$\ln\left(\ln\frac{100}{100-\Delta m}\right) = \ln\left(\ln 1\,00/(100-\Delta m)\right) \qquad (6)$$

from temperature T, K.

In Fig. 1 shows a graphical dependence of the rate of destruction of wood on the inverse temperature. The value of the activation energy (E) is calculated depending on:

$$E = \text{tg}\phi \cdot R \qquad (7)$$

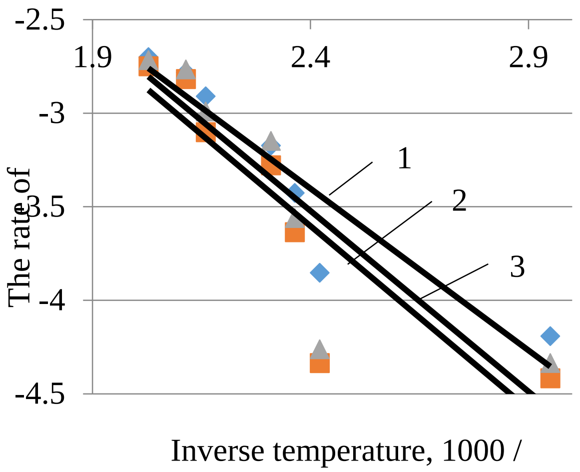

Fig. 1. Graphic dependence of the rate of thermal destruction of wood on the inverse temperature: 1 – pine; 2 – hornbeam; 3 – ash.

Table 2 shows the results of thermal analysis and calculation of the parameters required to determine the activation energy of the treated wood.

As can be seen from Table 3, pyrolysis of hardwood requires more activation energy, and therefore requires costs in its thermal modification, namely time and temperature.

One of most interesting property of heat-treated wood remains its decay resistance. Durability test with modified wood in laboratory are expensive and time-consuming. This review displays data from different analytical methods, such as spectroscopy, thermogravimetry, chemical analyses or mechanical tests that have the potential to be valuable indicators to assess the durability of heat treated wood at industrial scale. However, each method has its limits and drawbacks, such as the required investment for the equipment, reliability and accuracy of the results and ease of use at industrial scale.

Number in order	Wood	Activation energy, E, kJ / mol
1	Pine	13,47
2	Hornbeam	23,28
3	Ash	19,95

There is a partial increase in the values of most properties at a lower treatment temperature, eventually leading to the preservation of values at the level of untreated wood. Thus, for birch, the modulus of rupture increased by 26%, the modulus of elasticity by 24%, and the hardness in the radial plane by 34%. This is related to the fact that chemical changes are not yet significant, and they only case the restriction of the wood's ability to absorb bound water.

With higher treatment temperatures, there is a decrease in the elastic and especially the strength properties of the heat-treated wood. At higher treatment temperatures, more markedly right above 200 °C, the significant reduction of equilibrium moisture has no such effect as the consequence of more significant changes in the chemical structure of wood and the decrease in properties is significant.

Apparently, wood with a higher hemicellulose content, i.e., a lower overall resistance, exhibits a lower density, static bending strength, and toughness. Therefore, a more significant decrease was observed for the beech and birch woods than for the softwoods at higher treatment temperatures. The decrease of toughness by about 81% for beech wood with treated temperatures of 210 °C was observed in comparison to untreated wood (respectively 86% at birch). Static bending strength at heat treated birch wood decreased by 47% (respectively 59% at beech) [25-27].

The higher strength resistance (respectively mainly hardness) of birch wood compared to beech in relation to heat treatment has been demonstrated, which is probably due to the higher content of mannan fractions of hemicelluloses) [28-30].

The existing correlation between static and dynamic modules of elasticity was confirmed, but it was not statistically significant in all cases.

Our research confirmed that although untreated birch wood is not equal to beech wood from the view of wood properties, the heat treatment provides wood of similar properties. The impact of the heat treatment on the wood properties is less pronounced in the case of birch than beech, and the birch is thus more suitable for thermal modification. This simple and environmentally friendly method provides one of the ways to increase the utilization of birch wood in the industry for more valuable products than fuelwood.

Thermal modification of wood is an environment-friendly alternative method for improving several properties of wood without the use of chemicals. This paper deals with the examination of color and chemical changes in spruce (Picea abies L.) and oak wood (Quercus robur F.) that occur due to thermal treatment. The thermal modification was performed at 160 °C, 180 °C and 210 °C according to thermowood process. The color changes were measured by the spectrophotometer and described in the L*a*b* color system. Chemical changes were examined by wet chemistry methods, infrared spectroscopy and liquid chromatography. During the experiment, oak samples showed smaller color changes than spruce samples at all temperature values. During thermal modification, the content of cellulose, lignin and extractives increases, however the hemicelluloses content drops by 58.85% (oak) and by 37.40% (spruce). In addition to deacetylation, new carbonyl and carboxyl groups are formed as a result of oxidation. Bonds in lignin (mainly β-O-4) and methoxyl groups are cleaved, and lignin is condensed at higher temperatures.

Conclusion

Thus, the calculation revealed that the thermal decomposition of pine wood requires much less activation energy than the decomposition of hornbeam and ash wood.

The research results will also further signifies our strong resolve problems concerning the development of new means and methods of obtaining organic materials and operating conditions at different sites.

Authors express their gratitude to the Ministry of Education and Science of Ukraine for financial support of the research, that was performed in the framework of budget funding No. 3 DB-2018, as well as for the development of the theme of research according to the program of scientific cooperation COST Action FP 1407 "Understanding the modification of wood through an integrated scientific and environmental approach" of the European Union’s framework program HORIZON 2020.

Abstract. The article presents the main results of experimental studies on the identification of the main grade defects of oak lumber by the thermal non-destructive testing method. Regressional dependences of wood defects temperature display from the main factors for the studied grade defects are proposed. Indicators of infrared radiation (temperature range) of the main visible oak grade defects obtained as a result of experimental studies are presented. A conceptual scheme for the line control methods of identification of the main grade defects in lumber are proposed.

1 Introduction

Production of high-quality materials, determination of their properties today special attention is paid [1-6]. The full technological cycle is characteristic feature of the production of hardwood timber blanks in Ukraine – from round timber to finished intermediate products of final moisture content, since the manufacturing of such products from industrial wood is low cost-effective. In addition, in view of the very different size and quality characteristics of raw materials and the chaotic discrete location of wood defects in industrial wood, the technological process of cutting boards into blanks is characterized by considerable labor and material consumption, in which wood losses can reach 40 %.

The search of ways to increase the production efficiency of round oak timber blanks is a rather labor – demanding process and has traditionally been considered as two directions – cutting logs into industrial wood, and obtaining blanks from boards. The problem in the technology of the billets production at the stage of cutting freshly industrial wood is the significant complicacy in predicting the useful and high-quality billets without the use of effective non-destructive methods of assessment of the size and quality parameters of boards.

Modern scientific and technological achievements in the field of electronics and computer technology have led to a decisive revolution in the field of technological processes automation of sawmilling and woodworking in general. One of such scientific and technical solutions is the assessment of forest quality and sawn products by non-destructive testing methods (NDTM) before cutting them [7].

It is now possible to obtain this or that information about wood, to reveal surface or internal defects (knots, cracks, rot, various kinds of stains) using such NDTM as: optical scanning; laser scanning; ultrasound scanning; X-ray; ST scan; microwave scan; infrared scanning etc. It is known that the most effective NDTM for assessing the quality of lumber are: acoustic, radiation and thermal scanning methods [8]. Moreover, the acoustic and radiation methods are based on measuring the wood density, which allows us to assess the real shape, as well as the existing surface and internal defects of industrial wood without destroying the wood. However, they have a common drawback – high cost and, in most cases, are used to assess the quality of dry industrial wood [9-12].

Therefore, in order to reduce the cost of the process of non-destructive quality control of industrial wood, in this report we consider the hypothesis of possibility of using thermal NDTM to reveal and identify wood defects in industrial wood of oak of initial moisture content, based on statements regarding the different structure, heat capacity and humidity of defect-free wood and wood with defects [13, 14]. Profile densities of two types of imported solid wood flooring from lumber were quickly detected by their physical properties and basic chemical compositions using fast detection technology, X-ray scanning method and infrared spectrum with Fourier transform [15].

Scanning logs in industrial computed tomography provides detailed information about the quality of wood before sawing [16-18]. And near-infrared spectroscopy in combination with multidimensional statistical modeling can be a suitable forecasting model for determining the manufacturing quality [19].

An approach to computerized classification is proposed, which uses a hybrid approach using predicted profit-making capacity from slice-modeling and neural-network methods for increasing both accuracy and high processing speed [20]. Non-destructive logs scanning using georadar to detect defects in logs before sawing can

* Corresponding author: bondolya3@gmail.com

significantly increase the productivity and output of high-quality defect-free industrial wood due to the optimal orientation of the saw blade and prevent damage of the saw blade from incised metals [21].

Numerous energy crop species and various processing methods provide thousands of biomass samples that need quick, low-cost analysis. Infrared methodology can provide high-throughput analysis of cellulosic biomass. The conventional method for biomass analysis is time-consuming, labor-intensive and unable to provide structural information. Use of infrared spectroscopy allows qualitative and quantitative analysis of biomass samples without destruction of samples, which is beneficial for in situ or in-field measurement. Chemometric analysis is able to make calibration models robust and reliable. The progress of infrared techniques and their applications in biomass study is introduced. A comparison of infrared methods and the conventional method is also summarized. We also review recent infrared applications in biomass analysis and discuss the prospects for applications of infrared techniques [22-24].

Raman spectroscopy is a technique that can detect and characterize a range of molecular compounds such as water, water ice, water-bearing minerals, and organics of particular interest to planetary science. The detection and characterization of these molecular compounds, which are indications of habitability on planetary bodies, have become an important goal for planetary exploration missions spanning the solar system. Using a compact portable remote Raman system consisting of a 532 nm neodymium-doped yttrium aluminum garnet (Nd:YAG) pulsed laser, a 3-in (7.62 cm) diameter mirror lens and a compact spectrograph with a miniature intensified charge coupled device (mini-ICCD), we were able to detect water (H_2O), water ice (H_2O-ice), CO_2-ice, hydrous minerals, organics, nitrates, and an amino acid from a remote distance of 122 m in natural lighting conditions. To the best of our knowledge, this is the longest remote Raman detection using a compact system. The development of this uniquely compact portable remote Raman system is applicable to a range of solar system exploration missions including stationary landers for ocean worlds and lunar exploration, as they provide unambiguous detection of compounds indicative of life as well as resources necessary for further human exploration [25-29].

Recently usage of timber in various industries is impossible without knowledge of its structure and physical and mechanical properties. It is therefore important to investigate the hardwood timber structural features and set the main parameters that characterize its quality and strength. The use of special non-destructive methods for assessing the lumber quality (ultrasonic, optical, laser scanning) allows measuring the real shape, presence of the surface and internal defects without timber destruction. Information obtained by dimensional and qualitative characteristics is considered when the introduction of CAD for optimal cutting. Comparing the results of the plate lumber cutting without the use of optimized systems and with cutting optimization (CAD), it can be seen that the output is useful when cutting plate materials without the use of CAD is 85 % and the plate lumber yield with the use of CAD is 90-95 %. Results of work pieces yield using lumber scanning showed that yield when cutting increases up to 10 %, confirming the rational choice of method for assessing the lumber quality [30].

Thus, the research on revealing and identification of the main wood grade defects is trending.

The purpose of this work of the study was the research on revealing and identification by the thermal NDTM of the main grade defects of wood in initial humidity of industrial oak wood.

2 Raw materials and methods

Industrial oak wood was used for research.

A control scheme has also been developed to identify the main grade defects of wood in freshly sawn industrial oak wood, shown in Fig. 1.

The control circuit provides the use of photo filters (RGB) for capturing the certain infrared radiation wavelength of the industrial wood defects after being blown with hot air.

Analysis of functional dependencies of industrial oak wood stimulation.

It is known that various types of lamps, heat guns and lasers can be the methods of thermal stimulation of the studied material. A general comparison criterion for various thermal control procedures is the signal-to-noise ratio, which can be determined by the formula [31]:

$$S = \frac{\overline{T}_d - \overline{T}_{nd}}{\sigma_{nd}}, \tag{1}$$

where is the

$\overline{T}_d$ – average temperature of the defective zone, °C;

$\overline{T}_{nd}$ – average temperature of the defect-free zone, °C;

σ_{nd} – standard deviation of the defect-free region (noise variance), which is determined by the equation:

$$\sigma_{nd} = \sqrt{\sum_{i=1}^{n} \frac{(T_{ndi} - \overline{T}_{nd})^2}{n-1}}. \tag{2}$$

It was established that internal defects can be detected provided that upon observation the signal caused by them exceeds the noise level:

$$S > 1. \tag{3}$$

It is known that internal defects of the material can be detected by the thermal method if a combination of the following conditions is fulfilled:

$$\Delta T(\tau_m) > \Delta T_{res}, \tag{4}$$

$$C(\tau_m) > C_{noise}, \tag{5}$$

$$T_{abs}(\tau = \tau_h) < T_{destr}, \tag{6}$$

Conditions (4-6) are based on the parameters: equipment (devices), ΔT_{res}; products, C_{noise}; heating, T_{abs}; defects, ΔT or C.

Thus, in order to establish the most effective method of industrial wood thermal stimulation of oak wood initial moisture, we determined the signal-to-noise ratio criterion, S, using equations (1-2) and verified the fulfillment of conditions (3-6), for which a number of experimental studies were performed. For the experiment, uncut industrial wood from oak timber was selected in an amount of 720 pieces with an average initial moisture content (40…50%), an actual thickness of 30 mm and a length of 1.7 m.

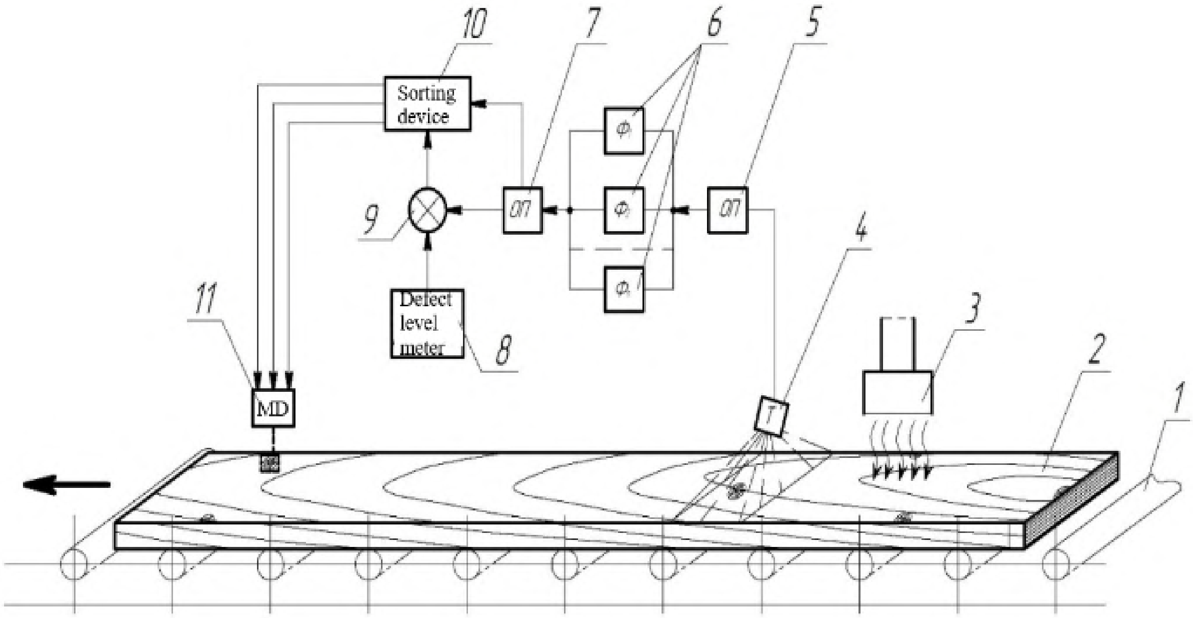

Fig. 1. Schematic diagram of the control method for identifying the main grade defects of wood in industrial wood: 1 – roller conveyor; 2 – industrial wood; 3 – installation of warm air supply; 4 – photo-video thermal imager; 5 – computing device; 6 – photo filters; 7 – computing device; 8 – defect level meter; 9 – adder; 10 – sorting device; 11 – marking device.

3 Results and discussion

To determine the most practical and inexpensive method of thermal stimulation, an experiment was conducted in which the studied industrial wood samples were heated by two methods – incandescent lamps and a heat gun (industrial hair dryer). Laser heating was not foreseen in the experiment, due to its high cost, large dimensions and low efficiency. Thermal imaging of samples heated with a heat gun for 20 s is presented in Table 1. Image of the thermal radiation of the sample after cooling for 60-180 s is presented in Table 2.

Thus, the most effective method of thermal stimulation for performing a series of experimental studies on the identification of the main wood grade defects in industrial oak wood is the method using a heat gun (S=2.6). In the process of research work in using thermal NDTM to identify grade wood defects in oak of initial moisture content, the following indicators of infrared radiation defects were obtained: knots – t = 16…24 °C, rot – t = 22…27 °C, cracks – t = 24…31 °C.

When heating industrial wood, there is a clear difference between the thermal radiation of defect-free wood and areas with violations, which can be explained by the following reasons: different heat capacity of wood and fixed defects; different humidity of individual sections of lumber; heterogeneity of the structure of wood, affects its emissivity.

The radiation temperature range of the main variety-forming wood defects at the corresponding blowing temperature (air) and blowing time is shown in Fig. 2.

Table 1. Part of the data set of experimental studies of the parameters for assessing the quality of oak lumber after heating.

Number in order	Digital image sample	Image of the thermal radiation of the sample before the experiment	Image of the thermal radiation of the sample after heating through 20 s
1			2			3			
As a result of experimental studies, overlapping of the infrared reflection temperature ranges of the studied wood defects was noted (Fig. 3); therefore, to clearly capture a certain wavelength range of infrared (thermal) radiation from lumber defects, it is proposed to use RGB filters for a certain radiation wavelength spectrum.

Table 2. Part of the data set of experimental studies of the parameters for assessing the quality of oak lumber after cooling.

	60 s	120 s	180 s
1			2			3			

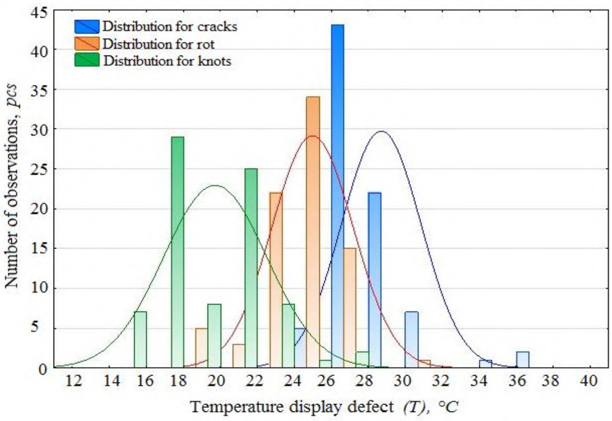

Fig. 2. Temperature range for displaying grade defects of wood when blown with air at 80 °C.

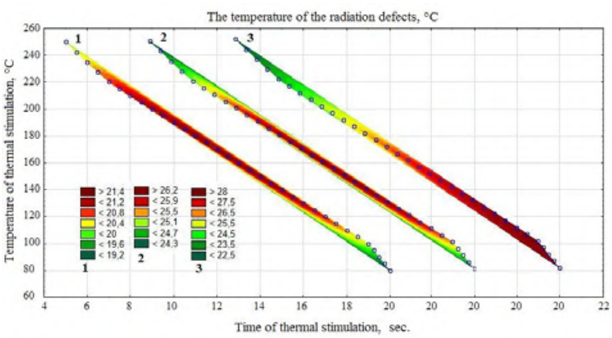

Fig. 3. The temperature distribution ranges of the display of the main variety-forming wood defects in oak lumber at a temperature of thermal stimulation: 1 – knots; 2 – rot; 3 – cracks.

Based on the research results, we obtained the regression dependences of the defects display temperatures on the main factors presented in normalized values for each of the variety-forming defects:

– knots: $y_k = 22{,}23 - 3{,}38x_1 + 2{,}98x_2 - 2{,}13x_1x_2$, $(F_{calc.} = 0{,}10; F_{tabl.} = 1{,}3)$, (7)

– rots: $y_r = 26{,}85 - 4{,}25x_1 + 4{,}40x_2 - 2{,}10x_1x_2$, $(F_{calc.} = 0{,}11; F_{tabl.} = 1{,}3)$, (8)

– cracks: $y_c = 26{,}75 - 2{,}75x_1 + 5{,}85x_2 - 1{,}25x_1x_2$, $(F_{calc.} = 0{,}16; F_{tabl.} = 1{,}3)$, (9)

where is the

x_1 – temperature of thermal stimulation of industrial wood by air, °C; x_2 – duration of thermal stimulation of lumber, s.

To select operational parameters of the identification process for each of the studied oak wood defects in freshly sawn timber, the scale is proposed to determine the time of thermal stimulation (τ, s) and the temperature of the wood defects display (t, °C) depending on the temperature of thermal stimulation (T, °C) (Fig. 4).

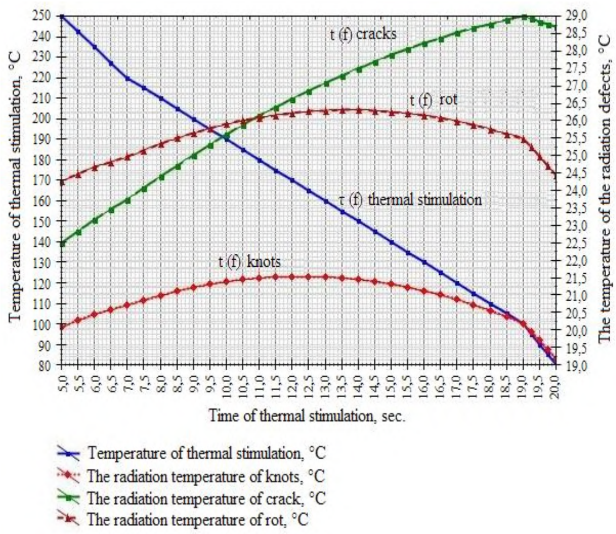

Fig. 4. The scale for determining the time of thermal stimulation (τ, s) and the radiation temperature of wood defects (t, °C) depending on the change in the temperature parameter of thermal stimulation (T, °C).

The duration of the photothermal imaging process for assessing the size and quality characteristics of industrial oak wood of initial moisture per running meter was established, which is in the range from 19 to 64 s with a fixing interval of 2 s, provided that the width of the board is not more than 350 mm and the scale factor is (K_m) – 6 (Fig. 5).

To carry out the research on the identification of oak wood defects in lumber of initial moisture content, a method and line were developed and proposed (Fig. 6) for the thermal non-destructive detection of defects, which are based on the use of photo-video thermal imaging of material surfaces and a hot air blowing lumber installation.

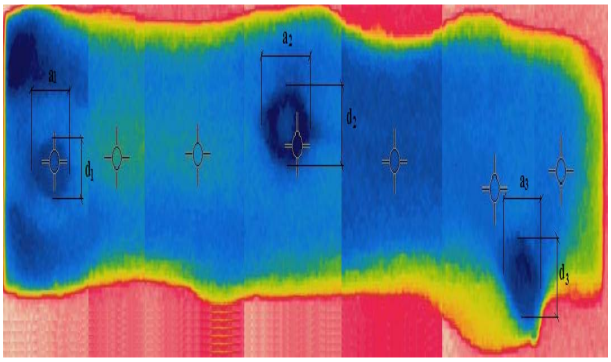

Fig. 5. An experimental study of the assessment of the quality of industrial oak wood using a thermal non-destructive testing method.

c

Fig. 6. The line of thermal non-destructive identification of variety-forming defects of lumber: a – frontal projection; b – horizontal projection; c – section AA frontal projection.

The line for thermal non-destructive detection of grade defects of industrial wood has: a roller conveyor 1, a support roller conveyor 2, pinch rollers 3, a drive pinch roller 5, an installation of blowing lumber 4 with hot air 6, a nozzle for the direction of air movement 7, horizontal guides 8 of the mechanism for regulating the photo and video heater 9 relative to the installation 6, the guides 10 of the mechanism for adjusting the distance of the video and thermal imager 9 in height and width of lumber 4, corrugated pipe d 11 blowing agent supply timber (hot air), the upper guide 12 and lower guide 13 for adjusting the mounting mechanism 6 in the thickness range of timber, the guide mechanism 14 for adjusting the distance setting adjustment timber 6.Based on the results of the studies, in order to increase the efficiency of the use of wood raw materials, recommendations were developed for manufacturers of oak billets.

4 Conclusion

The results of experimental studies have confirmed the practicability of using the thermal control method to identify the main grade wood defects in oak timber by thermal imaging using heat stimulation by guns, the effectiveness of which is established by the signal-to-noise (S) criterion.

Regression dependences of the temperature of infrared radiation of grade defects of wood on the temperature and time of thermal stimulation of the board have been obtained, on the basis of which the scale for predicting the temperature of defect radiation has been developed, which allows to control the process of grade defect`s identification.

The practical implementation of the research results is presented by the developed method and the line for the thermal non-destructive identification of grade wood defects in industrial wood, for which the control identification defects method have been developed and proposed.

Authors express their gratitude to the Ministry of Education and Science of Ukraine for financial support of the research, that was performed in the framework of budget funding No. 3 DB-2018, as well as for the development of the theme of research according to the program of scientific cooperation COST Action FP 1407 "Understanding the modification of wood through an integrated scientific and environmental approach" of the European Union’s framework program HORIZON 2020.

Abstract. The work is devoted to the problem of increasing gas condensate production in gas condensate fields. It was found that ammonium carbonate salts, in the absence of calcium chloride type waters, interact with carbonate rocks, increase the permeability of reservoirs. Solutions of ammonium carbonate salts when interacting with formation water of the calcium chloride type form chemically precipitated chalk in the pore space, while the permeability of carbonate rocks decreases. A set of experimental studies was carried out to study the displacing and washing properties of ammonium carbonate salts. It was found that ammonium carbonate salts have high displacing properties, the displacement ratio of kerosene by NH_4HCO_3 solution is 0.75-0.80, while reservoir water – 0.55-0.58. According to the results of laboratory studies of the displacing and washing characteristics of ammonium carbonate salts, conclusions were made about the effect of bicarbonate solution (ammonium carbonate salts) on the production characteristics of a well in reservoir conditions at temperatures of 80-100 °C and above. Industrial tests of ammonium carbonate salts showed an increase in gas flow by 30-50% at wells № 23 of Opishnia, № 115 of Mashivka, № 3 of Tymofiivka gas condensate fields. The effect of formation treatment with ammonium carbonate salts is achieved due to clearing of well bottom zone and increasing the formation permeability. At wells № 56, 108 of Yablunivka and № 58 of Tymofiivka gas condensate fields, an increase in the condensate ratio was observed by 22-35%. The effectiveness of this treatment is associated with the simultaneous bottomhole zone cleaning from asphalt-resinous contaminants and permeability increase, as well as with the hydrophilization of the pore space and mobility increase of condensate precipitated as a result of carbon dioxide effect, which was rejected as a result of decomposition of ammonium carbonate. Thus, experimental and industrial tests in Opishnia, Mashivka, Tymofiivka, Yablunivka gas condensate fields of Poltava region confirmed the effectiveness of using ammonium carbonate to increase hydrocarbon production. The prospect of further research is aimed at developing a technology for increasing the production of liquid hydrocarbons by using ammonium carbonate salts.

Introduction

Ukraine has significant deposits of developed mineral deposits. To date, 90 types of minerals have been explored, which are concentrated in almost 8000 deposits. For sustainable development it is necessary to increase the efficiency of natural resources [1, 2, 3].

Today, most of the gas, gas condensate and oil fields in Ukraine are at the final stage of development, the production of gas and liquid hydrocarbons is decreasing.

One of the urgent problems of the oil and gas industry is to improve the efficiency of wells operation. In modern conditions, the solution to this problem is largely determined by the timely development, justification and targeted application of new technologies to improve the efficiency of hydrocarbon extraction.

The development of gas condensate fields for depletion is accompanied by a decrease in reservoir pressure and retrograde condensation of high-boiling *C5+* hydrocarbons (condensate) with the loss of some of them into the liquid phase and their loss in the reservoirs, due to the fact that the condensate that precipitates in the reservoirs turns out to be stationary and is not involved in filtration processes.

As a result, up to 30-60% of the initial condensate reserves remain in the deposits [4-6]. In addition, there is clogging of the pores with rock particles, asphalt, resin, paraffin deposits [7-9].

Therefore, the search and substantiation of new methods of field development aimed at increasing the condensate recovery of the productive formation, at the same time, will ensure the cleaning of the bottomhole zone from pollution products and this is an urgent task.

At the first stage of development of oil and gas condensate fields, production is carried out due to the depletion of reservoir energy. This stage, called primary,

* Corresponding author: dmytr.v@gmail.com

 https://doi.org/10.1051/e3sconf/202128007011

makes it possible to extract from the underground reservoir only up to 10-25% of hydrocarbons [10]. The various methods developed later were primarily aimed at maintaining reservoir pressure – methods of secondary production, or to improve the conditions for the movement of hydrocarbons in the porous environment of the rock – methods of tertiary production. The latter include various approaches to increasing the recovery of liquid hydrocarbons from depleted and highly watered fields.

These methods and their variations, according to some estimates [11], have up to 250 names, including various schemes for the formation of excess pressure, injection of working media, thermal effects on the formation, chemical treatment of productive reservoirs, and the like.

One of the most effective ways to increase the recovery of liquid hydrocarbons from reservoirs is to inject water and CO_2 into the well [11-13]. With regard to the prospects for using the method of injecting carbon dioxide into the reservoir to increase oil and condensate recovery of depleted and highly watered fields, let us focus on the influence of the factor of carbon dioxide dissolution in water. Firstly, an aqueous solution of CO_2, entering into reactions and dissolving individual constituents of the rock, increases the permeability of the porous reservoir. Secondly, the viscosity of water increases, which leads to a decrease in its mobility, and together with an increase in the mobility of liquid hydrocarbons (through the dissolution of carbon dioxide in them), this contributes to the equalization of the mobility of water and liquid hydrocarbons, which is important for the efficiency of the process. Finally, changes in the properties of water and liquid hydrocarbons cause a decrease in the surface tension at «liquid hydrocarbons-water» interface and increase the wettability of the rock with water. All this in combination contributes to a more efficient washout of the hydrocarbon film. [14, 15].

According to 2000 estimates, there were 84 projects to enhance condensate and oil recovery by carbon dioxide injection in the world at the stage of implementation. Of these, 72 (96%) were carried out in the United States, which indicates its leadership in this important scientific and technological area. It is interesting that in work [16] the second place is given to Turkey, whose projects, according to expert estimates, allow counting on significant commercial success [16]. According to estimates, in 2014, 136 carbon dioxide injection projects are being implemented worldwide, carried out by 30 operators. Of these, 88 are considered successful, 18 are promising projects, the remaining 20 have recently started [17].

The use of carbonized water to enhance condensate and oil recovery is also known. The main advantage of the injection of carbonized water is the relatively low consumption of carbon dioxide during injection into the reservoir in comparison with other options for its use [18].

However, in both cases, pure liquefied carbon dioxide, a compressor, and special equipment for injecting liquefied gases and liquids saturated with gas at high pressures are required.

Based on the above, it can be assumed that a reagent containing 10-15% of chemically bound CO_2, which is release under formation conditions, can be highly effective.

Such a reagent is a salt of carbonate (carbonic) acid H_2CO_3, namely, bicarbonate and ammonium carbonate (NH_4HCO_3 and $(NH_4)_2CO_3$ respectively). Solutions of these salts decompose easily at temperatures of 40-90 ºC. Therefore, in some cases, it is more reasonable from an economic point of view to use reagents containing 10-15% of chemically bound carbon dioxide CO_2, which is released in reservoir conditions.

The aim of the work is to study the effect of ammonium carbonate on the filtration properties of the reservoir, displacing and washing out the properties of the solution of ammonium carbonate and the use of a new reagent to increase condensate recovery at the fields of the Dnieper-Donetsk basin.

Materials and methods

The object of the study is a 20% concentration of ammonium bicarbonate (ammonium carbonate) solution.

The influence of solutions of ammonium carbonate salts on the physical and lithological parameters of core samples, namely: permeability, porosity, size of pore channels, were studied at the UIPK-1M installation, for which the natural core was filled with ammonium carbonate salts at a concentration of 200 g/l at temperatures 30, 40, 50, 60, 70 ºC for 3 hours.

Core material from various oil and gas fields (Khukhra, Reshetniaky, Rybalske, Velyki Bubny, Novohryhorivka and Matlakhivka*)* was used as reservoir models that were studied, namely, sandstone samples of 15 pcs. with the diameter of 30 mm and length 30 mm, with a permeability of 0.051-1.320 μm^2 and open porosity, which was in the range of 9.5-22.7%. Table 1 shows the geography of the studied samples.

Permeability was determined on a stationary laboratory setup with a fixed side hydraulic compression of 3 MPa.

Ammonium carbonate salts were removed from the core samples: in one case – with distilled water, in another – with formation water. The completeness of washing was determined by the presence of ammonium and carbonate ions in the filtrate by the titrimetric method.

The displacing properties of ammonium carbonate salts were determined by the value of phase permeability in the core samples. Phase permeability was investigated on the UIPK-1M installation at temperatures of 20, 30, 40, 50, 60 °C.

The washing properties of the solution of ammonium carbonate salts were investigated as follows: during the experiments, a sample of asphaltene substances (AS) dissolved in acetone, which were taken from the Yablunivka gas condensate field, was placed in the studied formation model. Acetone was removed by heating the test layer to 45 °C.

After that, the formation model was washed with a solution of ammonium carbonate with a volume concentration of 20%. After each washing, the formation model was dried in a drying oven and the content of asphalt-resinous substances was determined by the gravimetric method. For comparison, another formation model was washed with formation water.

Research results

The results of studying the effect of ammonium carbonate solutions on the physical and lithological parameters of core samples are shown in Table 2, 3.

Analysis of the data shows that the samples, from which ammonium carbonate salts were removed by distilled water, increased the permeability value by an average of 18% relative to the initial values. The theoretical size of the pore channels also increased in all studied core samples.

In addition, the effect of NH_4HCO_3 solution on the carbonate content of the samples is observed. In almost all cores, it decreased by 47-52% from the initial values (Table 2). As a result of the experiments, it can be argued that the dissolution of carbonate cements with ammonium salts occurs according to the equation.

$$2NH_4HCO_3 \rightarrow (NH_4)_2CO_3 + H_2CO_3$$

$$H_2CO_3 \rightarrow CO_2 + H_2O$$

$$CaCO_3 + CO_2 + H_2O \rightarrow Ca(HCO_3)_2$$

In this case, insoluble $CaCO_3$ converted into soluble $Ca(HCO_3)_2$.

In the laboratory, a number of experiments were performed to dissolve dry chalk with 20% ammonium bicarbonate solution.

The results showed that under normal conditions, the solubility of $CaCO_3$ in NH_4HCO_3 reaches 0.85-1.12 g/l, and at a temperature of 60 ºC – 1.6-1.74 g/l. This indicates the solubility of carbonate cements, which contain a solution of ammonium bicarbonate in the core samples.

Based on the thermochemical conditions of this process, the solubility of carbonate cement will increase with increasing pressure, which is a positive characteristic of the effect of NH_4HCO_3 solution on carbonate rocks in formation conditions.

The second part of the core samples shown in Table 3, from which ammonium carbonate was removed by formation water, reduced the permeability value by 14-28%, the size of the pore channels also decreased.

The reason for this effect of ammonium bicarbonate solution on the permeability of the core samples is obviously a chemical reaction between highly mineralized water and ammonium bicarbonate with the formation and precipitation of a solid phase.

Laboratory studies carried out when mixing formation waters from gas condensate wells with a 20% ammonium bicarbonate solution showed that when the content of Ca^{2+} and Fe^{3+} in the formation waters is more than 0.5 mg-ion / l, as well as Mg^{2+} – 1.5 mg- ion/l and more, the use of ammonium carbonate is ineffective due to the formation of water-insoluble carbonates according to the scheme.

$$2NH_4HCO_3 + CaCl_2 \rightarrow CaCO_3 + 2NH_4Cl + CO_2 + H_2O$$

$$2NH_4HCO_3 + MgCl_2 \rightarrow Mg(OH)_2 + 2NH_4Cl + 2CO_2$$

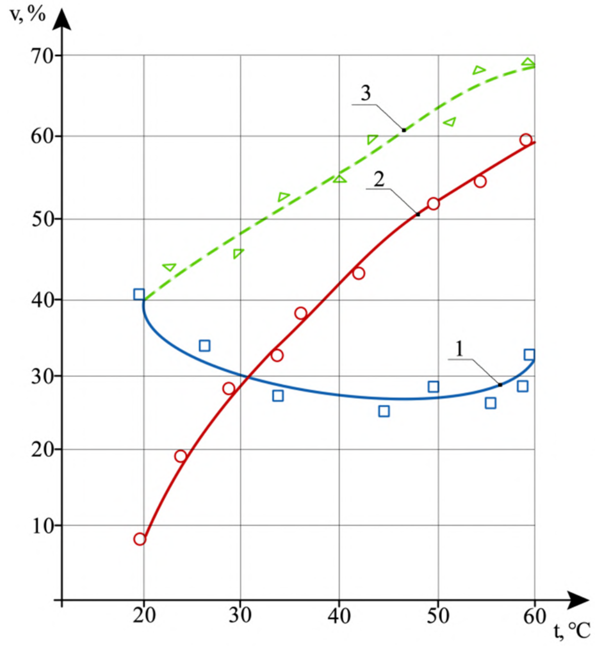

Fig. 1. Dependence of the relative permeability of core samples on temperature. Permeability: 1 – by solution of ammonium bicarbonate (in a sample of kerosene) 2 – by formation water (in a sample of kerosene), 3 – by air – (in a sample of kerosene).

Further research was aimed at studying the displacing properties of ammonium carbonate salts.

Table 4 shows the average values of the displacement coefficient, residual saturation, and relative permeability. From these data it follows that the relative permeability of the samples in descending order is as follows:

At a temperature of 20 °C:

1. by ammonium bicarbonate solution;
2. by air (in the kerosene sample);
3. by formation water (in the kerosene sample).

At a temperature of 60 °C:

1. by air (in the kerosene sample);
2. by formation water (in the kerosene sample);
3. by ammonium bicarbonate (in the kerosene sample).

Based on the results of experiments for displacing kerosene from core samples, graphical dependencies were built, which are shown in Fig. 1 and 2.

The low phase permeability of the core with respect to ammonium bicarbonate confirms the well-known phenomenon of an increase in the viscosity of aqueous solutions when they are saturated with carbon dioxide. It is known [19] that with an increase in the concentration of CO_2 in an aqueous solution up to 2.1%, the viscosity increases by 18.9%, and at a concentration of CO_2 up to 5.6% – by 27.2%.

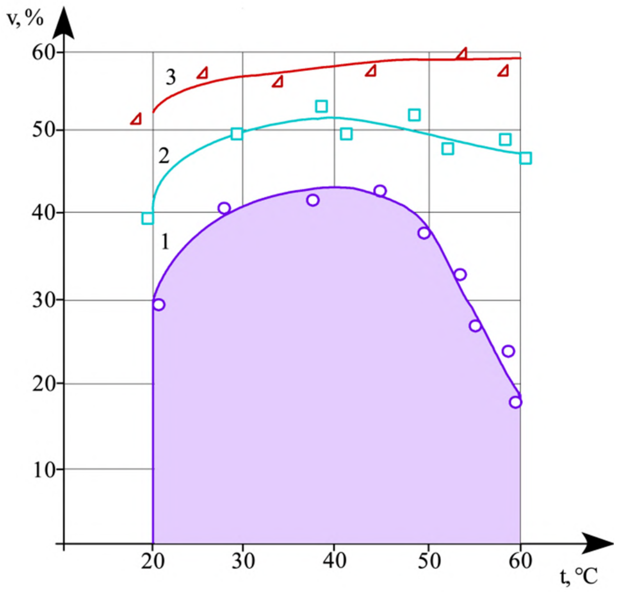

Fig. 2. Temperature dependence of the relative permeability of core samples. Displacement of kerosene from the core sample by: 1 – ammonium bicarbonate solution, 2 – formation water, 3 – air.

Analyzing the data shown in Fig. 2, it can be assumed that the increase in the temperature of the solution to 30-40 °C causes the release of some carbon dioxide, which initially pollutes the carbonate solution, increasing its viscosity, and at the same time blocks the pore space (Joumen effect). This, in turn, leads to a decrease in the phase permeability of the core to ammonium bicarbonate and low displacement of NH_4HCO_3.

However, a further increase in the temperature of the solution to 50-60 °C leads to an intensive release of carbon dioxide, which is dissolved in kerosene, changing its physicochemical properties. Studies show that as the temperature rises, the kerosene yield increases and the phase permeability of the degassed ammonia solution increases.

Further research is aimed at studying the washing properties of a solution of ammonium carbonate salts. During the experiments, a sample of asphaltene sediments (AS) dissolved in acetone, which were isolated from the Yablunivka gas condensate field, was placed in the studied formation model. Acetone was removed by heating the studied formation to 45 °C.

Table 4. The results of experiments to determine the coefficients of displacement, saturation and relative permeability.

№	**Characteristics of the experiment**	**Parameters**	**The results of the experiment**					
			Experiment temperature, ° C					
			20	**30**	**40**	**50**	**60**	**70**
1.	Displacement of kerosene by ammonium bicarbonate solution	displacement coefficient, β	0.75	0.60	0.57	0.68	0.80	–
		saturation coefficient, k_o	0.25	0.40	0.43	0.32	0.20	–
		relative permeability, k_i	0.40	0.35	0.26	0.26	0.33	–
2.	Displacement of kerosene by formation water	displacement coefficient, β	0.60	0.50	0.48	0.50	0.55	0.60
		saturation coefficient, k_o	0.40	0.50	0.52	0.50	0.45	0.38
		relative permeability, k_i	0.11	0.28	0.42	0.54	0.58	0.62
3.	Displacement of kerosene by air	displacement coefficient, β	0.47	0.43	0.41	0.40	0.37	–
		saturation coefficient, k_o	0.53	0.57	0.59	0.60	063	–
		relative permeability, k_i	0.40	0.45	0.52	0.62	0.66	–

Table 5. Influence of washing on the content of asphaltene sediments in the formation model.

Temperature, °C	**The content of asphaltene sediments, %**					
	Formation water			**20th solution of NH_4HCO_3**		
	Washing number			**Washing number**		
	1	**2**	**3**	**1**	**2**	**3**
20	86	79	53	12	4	0.1
40	72	51	23	4.5	0.1	–
60	60	29	10	1.6	–	–
80	45	11	0.2	0.3	–	–

The formation model was then washed with a solution of ammonium carbonate salts with a volume concentration of 20%. After each washing, the formation model was dried in an oven and the content of asphaltene sediments was determined by weight. For comparison, washing of another model formation was performed with formation water. The research results are shown in Table 5.

As can be seen from the table, the experiments were performed at temperatures of 20, 40, 60, 80 °C, and the formation model was washed three times. Analysis of the research results shows that the formation water only after the third wash at a temperature of 80 °C allows cleaning the formation from asphaltene sediments. At lower temperatures, the washing efficiency is low.

The use of a 20% solution of ammonium carbon dioxide as a washing liquid shows that even at a temperature of 20 °C after a single wash in the formation remains only 12% of asphaltene compounds. The efficiency of formation treatment increases with increasing temperature. From 40 °C begins the release of carbon dioxide, which, in turn, leads to increased purification of the pore space. At a temperature of 80 °C, the model formation is cleaned practically with ammonia water and carbon dioxide, which are formed during the decomposition of ammonium carbon dioxide salts.

The results of industrial tests

At the enterprises of GPD «PoltavaGasVydobuvannya» introduction of ammonium carbonate salts for treatment of the bottomhole zone of the formation was carried out. Investigations of wells after treatment were carried out on existing special research lines by the method of constant sampling in 5-6 modes of forward and 2-3 modes of reverse.

At the beginning of the test, the wells are flushed with 3-5% ammonia solution or ammonium bicarbonate, which are fed into the tubing or into the annulus. After that, the main intensification reagents are injected: ammonium carbonate salts.

The method of injection was chosen depending on the permeability of the collector. The working reagent was forced into the reservoir, kept there for 16-24 hours, then the well was developed in the barn and connected to the washing plant of complex gas treatment. After development and stabilization of the flow rate, the operating parameters of the well were removed.

The results of implementation showed that after treatment of productive reservoirs in wells № 23 of Opishnia and № 115 of Mashivka gas condensate fields (GCF) an increase in gas flow was obtained from 10 to 33.8 thous.m^3/day and from 15 to 30.4 thousand m^3/day, and at well № 3 of Tymofiivka gas condensate field increase in gas production amounted to 80 thous. m^3/day (Table 6).

Thus, the effect of bottomhole zone treatment of the formation with ammonium carbonate salts was achieved due to the cleaning of the bottomhole zone of the formation and permeability increase of reservoir.

Another effect of well intensification with NH_4HCO_3 reagent is a significant increase in the condensate factor with some reduction in gas flow. Thus, at well № 56 of the Yablunivka gas condensate field, the condensate factor increased from 54.8 to 80.9 kg/thous.m^3. The gas productivity after intensification decreased from 180 to 130-140 kg/thous.m^3. In the second month of well operation, after treatment of the reservoir, an increase in gas flow was observed, which is 55 thous. m^3/day more than the initial values. Treatment of this well shows that the proposed reagent obviously increases the mobility of the condensate. The formation was hydrophilized with the displacement of liquid hydrocarbons from the pore channels, as evidenced by a sharp increase in condensate flow. After cleaning the reservoir, gas production was increased.

Table 6. Influence of intensification on well productivity.

Period	**Gas flow rate** Q_g **thous. m^3/day**	**Condensate factor** *CF* **kg/thous. m^3**	**Condensate flow rate** Q_c**, before treatment and calculation without taking into account** *CF* **t/day**
Before treatment	14.7	69.1	1.01
After treatment	95.14	69.1	6.6
1 month	90.6	69.1	6.2
2 month	50.6	69.1	3.5
3 month	15.0	69.1	1.03

Table 7. Influence of intensification on well productivity.

Period	**Gas flow rate** Q_g **thous.m^3/day**	**Condensate factor** *CF* **kg/thous. m^3**	**Condensate flow rate** Q_c **before treatment and calculation without taking into account** *CF* **t/day**	**Condensate flow rate** Q_c **after treatment t/day**	**Condensate flow rate** Q_c **t/day**
Tymofiivka GCF, well № 58					
Before treatment	80.0	101	8.1	–	–
After treatment	122.8	117	12.4	14.4	2.0
1 month	120.0	128	12.1	15.4	3.3
2 month	110.0	120	11.1	13.2	2.1
3 month	100.0	119	10.1	11.9	1.8
4 month	100.0	108	10.1	10.8	0.7
5 month	90.0	108	9.0	9.7	0.7
Yablunivka GCF, well № 108					
Before treatment	290	55	15.8	–	–
After treatment	200	71	10.9	14.2	3.3
1 month	322	80	17.6	25.8	8.2
2 month	316	74	17.3	23.5	6.2
3 month	314	70	17.1	22.3	5.2
4-6 months	310	68	16.8	20.9	4.7
7-9 months	307	60	16.0	18.6	2.6
10 months	290	55	15.9	–	–

The most efficient is the treatment of wells № 58 of Tymofiivka and № 108 of Yablunivka gas condensate fields. The data given in Table 7, indicate that in both wells after treatment increased gas flow rate and condensate factor. The gas flow rate gradually decreased to the initial values, while the condensate factor remains high.

The effectiveness of this treatment is obviously associated with the simultaneous cleaning of the bottomhole zone from asphalt-resinous contaminants and an increase in permeability, as well as with the hydrophilization of the pore space and an increase in the mobility of condensate precipitated as a result of exposure to carbon dioxide, which was released as a result of decomposition of ammonium carbonate.

Conclusions

1. Ammonium carbonate salts, in the absence of calcium chloride type waters, interact with carbonate rocks,

increase the permeability of reservoirs due to the conversion of insoluble $CaCO_3$ to soluble $Ca\ (HCO_3)_2$.

2. Ammonium carbonate salts have high displacing properties, the coefficient of displacement of kerosene with NH_4HCO_3 solution is 0.75-0.80, while reservoir water – 0.55-0.58.

3. The NH_4HCO_3 solution has good washing properties against asphaltene contaminants. So, after washing the reservoir with ammonium carbonate salts at a temperature of 20 °C, no more than 10-12% of asphaltene substances remain in the model reservoir, and more than 60% with water.

4. Experimental and industrial tests at Opishnia, Mashivka, Tymofiivka, Yablunivka gas condensate fields of Poltava region confirmed the effectiveness of ammonium carbonate salts use for increasing hydrocarbon production. Industrial tests of ammonium carbonate salts showed an increase in gas flow by 30-50% at wells № 23 of Opishnia, № 115 of Mashivka, № 3 of Tymofiivka GCF, an increase in condensate factor by 22-35% at wells № 56 Yablunivka, № 58 of Tymofiivka GCR. The prospect of further research is aimed at developing a technology for increasing the production of liquid hydrocarbons by using ammonium carbonate salts.

Abstract. Laboratory sintering of sinter charge based on hematite and magnetite iron ores of various sizes was carried out. The purpose of the study was to determine the effect of the type and size of the ore material on the gas permeability of the sintered layer, sintering performance and the need for fuel. The granulometric composition, cold strength, strength during recovery, and reducibility of the resulting agglomerate have been studied. Differences in the course of the process of agglomeration of hematite and magnetite ores at different sizes were revealed in the research. The established patterns have practical interest from the point of view of increasing the efficiency of the sintering process, improving the quality of the sinter and reducing the harmful impact on the environment.

1 Introduction

Along with magnetite ores, hematite ores are of significant value for ferrous metallurgy. Analysis of the mineral resource base of mining and metallurgical enterprises [1-3] indicates the prospects of their use to expand industrial reserves of iron-containing raw materials. However, the technology of their agglomeration has characteristic features that distinguish them from traditional magnetite raw materials [4,5]. Thus, the ability of hematite materials to pelletize in the composition of sinter charges is, as a rule, worse in comparison with magnetite ones, which is associated both with the low wettability of hematite and with the peculiarities of the surface structure of ore grains. Sintering of hematite ores requires increased heat consumption compared to the processing of magnetite ores and concentrates. This is due to the absence in hematite ores of a powerful internal heat source from the oxidation of FeO magnetite, as well as a higher temperature of the beginning of their melting [6].

Analysis of the results of studying the process of agglomeration of iron ores [7-10] showed that, despite the vast amount of information on the patterns of formation of the structure, mineralogical and phase composition of iron ore agglomerates, there is no single point of view either on the mechanism of formation or on the influence of individual factors on qualitative characteristics of iron ore sinters. This circumstance makes it necessary to study the conditions for obtaining iron ore sinter from hematite ore, depending on its size.

2 Purpose and tasks of research

The purpose of this study is to establish and compare the regularities of changes in the indicators of the sintering process and the quality of sinter from the size of hematite and magnetite ores and sinter charges based on them. To achieve this goal, the following tasks were set:

- determination of the influence of the size of ores and sinter charges on their gas permeability;
- determination of the influence of the size of ores and sinter charges on the productivity of sintering;
- determination of the dependence of the demand for solid fuel on the size of ores and sinter charges and the type of ore;
- determination of the influence of the size of ores and sinter charges on the strength of the finished sinter in the cold state, during recovery and on the recoverability.

3 Data and methods

To determine the effect of the type of ore, the study did not use a mixture of different ores, but two separate ores - ore A, containing 100 wt.% magnegite, and ore B, containing 94 wt.% hematite. For the experiments, both ores were scattered into six fractions. By mixing the individual fractions, various grain compositions were prepared. Figure 1, a shows the size of the mixtures of fractions of the individual ores. Table 1 shows data on the chemical composition of the individual fractions of the studied ores, and table 2 - data on the chemical composition of the mixtures.

https://doi.org/10.1051/e3sconf/202128007012

When mixing the fractions, it was proceeded from the fact that the distribution of the mixture by size was as close to normal as possible, as is usually observed in ores and after their grinding. This normal distribution in double logarithmic coordinates is expressed by straight lines. In the area known from industrial studies of the spread of the upper limits of the size and maximum fractions of fines for sinter ores, the composition of the mixtures was expressed by straight lines. Only in one case (experiments 8 and 17) there was no normal distribution; the composition of the mixture was expressed as a curved line. Upon further graphic evaluation of the data, the location of the points for these mixtures was somewhat different from the usual one.

The proportion of the –3 mm fraction in the prepared mixtures ranged from 0–36 wt.%, the –0.1 mm fraction - within 2.7–37.0 wt.%. The maximum grain size of the ore was 10 mm.

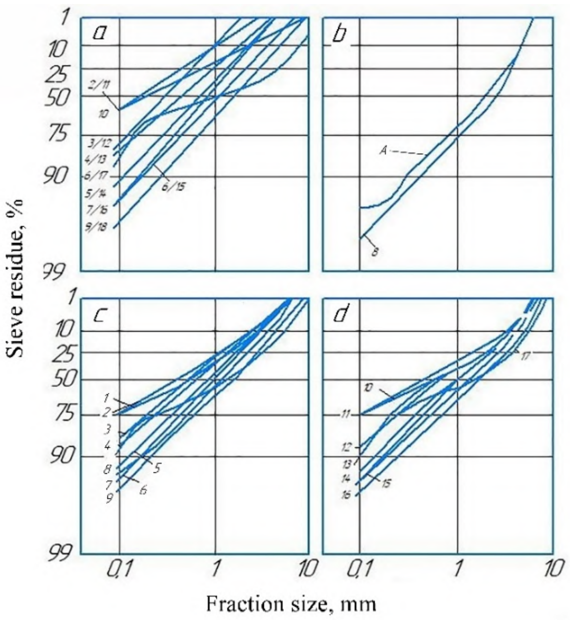

Fig. 1. Distribution of ore, return and sinter charge according to the size of fractions: a) mixtures of fractions of ores A and B; b) return for ores A and B; c) sinter charge based on ore A; d) sinter charge based on ore B. 1-9 - a mixture of fractions from ore A; 10-18 - a mixture of fractions from ore B

Table 1. Chemical composition of the fractions of the studied ores.

Fraction, mm	Substance, wt.%				
	Fe	Fe^{2+}	SiO_2	CaO	MgO
Magnetite ore A					
10-6	67.37	22.41	2.84	0.10	0.90
6-3	64.42	22.61	2.92	0,10	1.04
3-1	66.77	22.46	3,32	0.10	0.88
1-0.2	64.98	19.46	4.66	0.25	1.14
0.2-0.1	67.60	20.70	2,64	0.70	1.14
-0.1	61.19	20.37	6.63	1.44	2.32
Hematite ore B					
10-6	65.18	1.00	3.18	0.10	0.05
6-3	65.13	1.40	3.24	0.10	0.05
3-1	65.23	1.30	3.08	0.10	0.09
1-0.2	65.27	1.40	2.44	0.10	0.09
0.2-0.1	67.51	1.70	1.44	0.10	0.07
-0.1	63.82	1.25	6.10	0.10	0.28

To characterize the mixtures, the HS_{50} index was used – this is the mesh size of the strainer through which 50 wt.% of the mixture passes.

The iron content in all agglomerates was maintained at 58 wt.%. The basicity of all agglomerates (CaO / SiO_2), in turn, was maintained at 1.3, which was achieved by adding dolomite or ground limestone with a particle size of 0–3 mm. The MgO content in the finished agglomerate was to be 1 wt.%. The return addition was constant at 40 kg/100 kg ore. By varying the coke consumption, each experiment was carried out so that the return balance (the ratio of the return yield R_A to the return flow R_B) was 95-105 wt.%. The quality of additives and coke, as well as their size, were kept constant.

17	65.89	2.77	0.10	0.08
18	65.55	2.94	0.10	0.08

All experiments were carried out in a bowl with a suction area of 400×400 mm. The bed was a return with a size of 10–20 mm. The total height of the sintered layer was 300 mm. The vacuum during all experiments was kept constant at 800 mm of water. art. All mixtures were pelletized before being loaded into the bowl. The mixture was ignited at a temperature of 1150 °C. The duration of the experiment was considered the time from the start of ignition to reaching the maximum temperature of the exhaust gases plus 1 min. The agglomerate was then cooled by suction and dropped three times with a height of 2 m onto a steel plate. After dropping, a 6.3 mm square sieve was sieved to determine the return yield.

Sieve and chemical analyzes were performed for all finished agglomerates with equalized return balance. Then the agglomerate was subjected to drum tests, the destruction of the grains at the beginning of the reduction was investigated, and the recoverability was also determined.

4 Research results and discussion

When evaluating the research results, it turned out that the

 https://doi.org/10.1051/e3sconf/202128007012

return size fluctuated greatly. For each ore, based on all sieve recovery analyzes, a mixed sieve analysis was calculated, which is graphically presented in fig. 1, b. It was found that the return during sintering of hematite ore B has fewer fine fractions than the return during sintering of magnetite ore A.

The oxidation state of the return in individual experiments also fluctuated. It was determined by calculation. When using ore A, it was 94%, when using ore B - 97.3%. Thus, the dependence of the oxidation state of the return on the oxidation state of the charge is visible.

Since the return flow rate of 40 kg/100 kg of ore mixture was kept constant, the return had a significant effect on the properties of the entire mixture. In this regard, in fig. 1, c, d shows the size of the entire charge A and the entire charge B. In contrast to pure ores, significant changes are visible. All sieving curves are biased towards larger fractions.

As already mentioned, when graphically evaluating the research results for the characterization of ore mixtures or mixtures with return, it seemed most appropriate to use the HS_{50} indicator. In some cases, the best indicator was the content of the fraction –0.1 mm. The graphical assessment of the measurement results in all cases was carried out, firstly, in relation to the size of the ore used, and secondly, in relation to the size of the entire charge. The need for the latter is caused by a strong change in the size of the charge due to the addition of return.

4.1 Gas permeability of the charge in the sinter bowl

Fig. 2, a, b and d show the gas permeability of the sinter charge in the bowl as a function of the size of the ore and the entire charge. The intake air flow rate was measured before ignition and at the time corresponding to 60% of the sintering time.

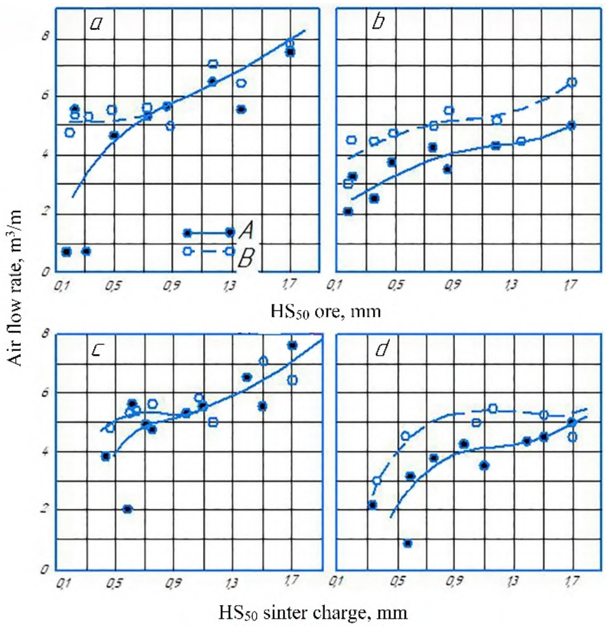

Fig. 2. Dependence of the gas permeability of the charge in the bowl on the size of the ore and sinter charge: a), c) before igniting the charge; b), d) after 60% of the sintering duration.

For both ores, a shift in HS_{50} values towards larger fractions was established during the transition from ore to to agglomeration. Before ignition, in all cases, an increase in gas permeability is observed with an increase in the grain size (Fig. 2, a).

For finer mixtures, there is a difference between the gas permeability of ores A and B: the gas permeability of ore B is higher than that of ore A. about 5 m^3/min, and for ore A - only 3 m^3/min.

The best gas permeability of hematite ore is observed when the particle size is HS_{50} = 0.7–0.8 mm or for the size of the entire charge HS_{50} = 0.9–1.0 mm. It was also found that for hematite ore these values in the area of fine fractions fluctuate strongly. The same picture is observed for the second moment of time (Fig. 2, b, d).

If in the area of coarse fractions these values lie very close to one another, then in the area of small fractions they differ significantly. The scatter area for ore A is also larger in this case. It was also found that the gas permeability of hematite ore in the area of very fine fractions by the second selected time point decreases much less than that of magnetite ore.

The higher gas permeability when using hematite ore can be explained by the greater strength of the lumps due to the adhesive components. With strong waterlogging of the sinter charge in the lower part of the bowl, less strong destruction of the formed lumps occurs here than during sintering of the charge from magnetite ore.

4.2 Sintering performance

Fig. 3 shows the dependence of the sintering performance on the size of the ore and sinter charge. Here, along with the HS_{50} index, the fraction content of –0.1 mm was also used as a parameter. As expected, sintering productivity increased with increasing ore size. At the same time, the difference between hematite and magnetite ore was not established. The achieved productivity was 40 t/m^2·day. In the same way as for gas permeability, differences between the two ores were found for the sintering performance in the area of fine fractions (Fig. 3, a and b). These differences are found when the value of the HS_{50} index for ores starting from 0.6 mm and for the entire charge starting from 1.0 mm, which coincides with the corresponding data for gas permeability.

With this method of assessment, the indicators with a fractional composition that did not correspond to the normal distribution (experiments 8 and 17) were very different from the rest of the data. Therefore, an estimate was adopted for the content of the fraction –0.1 mm. Fig. 3, b and d, it is clearly seen that with an increase in the fraction of –0.1 mm, productivity decreases. The difference is again noticeable for ores A and B in the area of fine fractions, and for ore - starting with a fraction of –0.1 mm 5 wt.%, and for the entire charge - starting with a fraction of –0.1 mm 7 wt.%. These differences can also be explained by the different lumpiness of the ore. It should be emphasized once again that all experiments were carried out with the same return content in the charge.

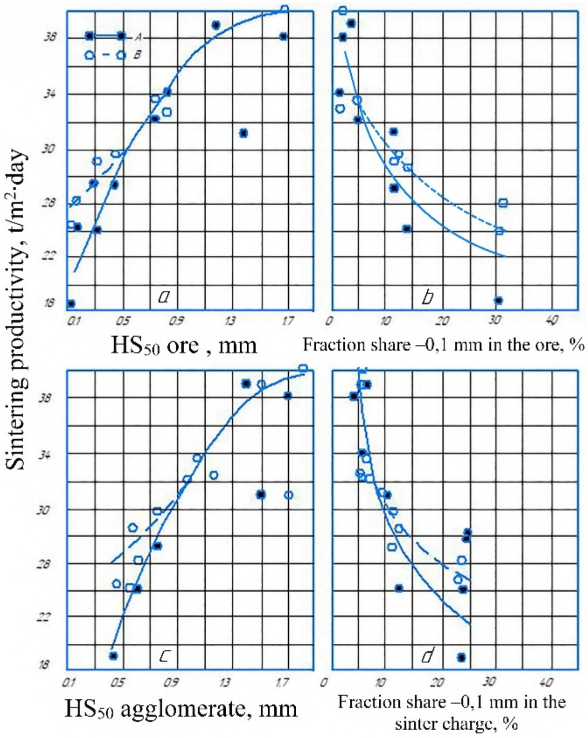

Fig. 3. Dependence of the productivity of sintering on the size of the ore and sinter charge

4.3 Moisture mixture

The moisture content of the mixture was determined by manual test. Upon subsequent determination of the moisture content, it was found that, as expected, it decreases with increasing grain size. However, the charge from hematite ore was found to have a significantly higher moisture content. It was 6.0–7.5 wt.%, and in the charge of magnetite ore – only 4.0–5.6 wt.%. From this it is seen that hematite ore in the area of fine fractions has a larger specific surface area than magnetite.

4.4 Fuel requirement

Fig. 4 shows the dependence of the demand for dry coke on the size of the ore and sinter charge. At the same time, there is a noticeable difference in the demand for coke for magnetite and hematite ores. On the other hand, the influence of the ore size is noticeable.

Starting with a certain grain size, the need for coke is constant or increases very slightly. Thus, with the value of the indicator HS_{50} for ore 1.1 and above, the need for coke for hematite ore B is 6.7 kg/100 kg of dry ore, and for magnetite ore - 4.7 kg/100 kg of dry ore (Fig. 4 , a).

The corresponding value of the HS_{50} indicator for the whole charge is 1.4 mm. With a smaller grain size, the need for coke in both cases decreases to a sharp minimum (especially for sinter charge), which is in the range of values of HS_{50} = 0.6–0.7 mm (Fig. 4, b). This minimum, related to the size of the ore, is sharply expressed for magnetite ore and is at a value of HS_{50} = 0.5 mm. In the area of even smaller fractions, a marked increase in the demand for coke was again found, both for magnetite and hematite ores.

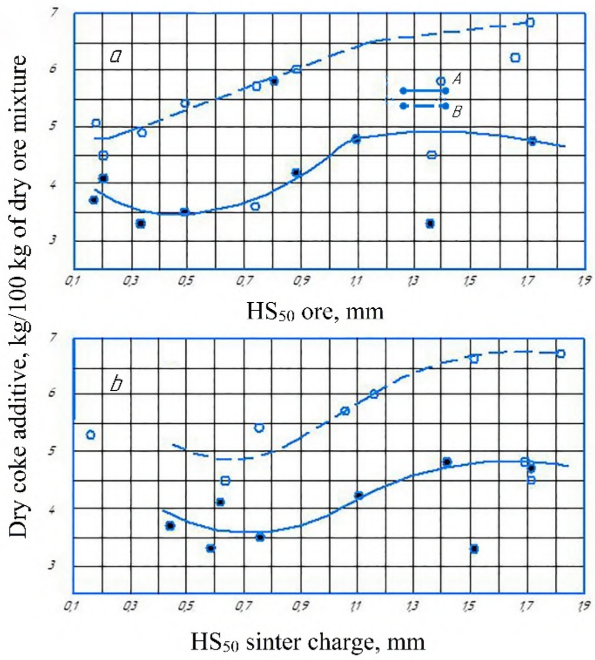

Fig. 4. Dependence of the need for coke on the size of the ore and sinter charge

4.5 Size of the finished agglomerate

The sieve analysis of the finished agglomerate clearly depends on the size of the sinter charge, but even in this case there are differences for hematite and magnetite ores. Fig. 5 shows the dependence of the content of the fraction +25 mm in the agglomerate on the index HS_{50}. In the area of smaller fractions, the points for hematite and magnetite ores are located closer to each other and in both cases in this area the data scatter is larger.

With an increase in the size of hematite ore B, a continuous decrease in the yield of the agglomerate fraction of +25 mm is observed, while for magnetite ore A, starting with an HS_{50} of 0.8 mm (for a sinter batch of 1.0 mm), this value remains constant. In general, the yield of the +25 mm fraction in the agglomerate from magnetite ore is higher than from hematite, which indicates their different sintering capacity.

4.6 Drum strength

An agglomerate sample weighing 15 kg was loaded into a drum 1000 mm in diameter and 500 mm in length and ground in 200 revolutions at a rotation speed of 25 rpm. After that, sieving was carried out into fractions +6.3 and –0.5 mm. The proportion of the +6.3 mm fraction characterizes the drum strength, the proportion of the –0.5 mm fraction characterizes abrasion.

Tests have shown that the abrasion of the agglomerate from hematite ore is 7.6–5.3 wt.% and there is a tendency to decrease it with an increase in the size of the ore. For agromerate from magnetite ore, abrasion is 8.0–6.4 wt.%, and in this case there is also a tendency to decrease it with an increase in the size of the ore. The maximum abrasion was observed at an HS_{50} value for a charge of 0.6–0.7.

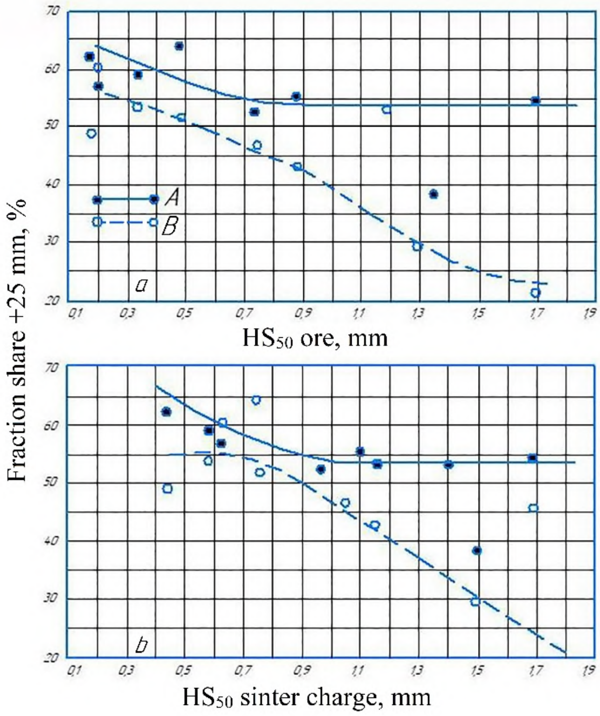

Fig. 5. Dependence of the +25 mm fraction content in the finished agglomerate on the size of the ore and sinter charge

Fig. 6 shows the dependence of the drum strength (fraction yield + 6.3 mm) on the size of the ore and charge. It should be noted that the strength of 41– 53 wt.% for agglomerate from magnetite ore and 46–58 wt.% for sinter from hematite ore cannot be considered satisfactory. These results can be explained by the basicity of the fluxed agglomerate at the level of 1.3, which often leads to a decrease in strength indicators.

However, attention is drawn to the fact that agglomerates from magnetite ore A and from hematite ore B have different strength values and the nature of its dependence on the size of the ore and sinter charge. In the agglomerate of magnetite ore A, with an increase in size, an increase in strength is first observed to reach a maximum at HS_{50} = 0.6 mm for the ore and 0.8 mm for the charge. Then, with an increase in size, a constant decrease in strength is observed, and in the area of the largest fractions, the strength indicators turn out to be lower than in the area of the smallest fractions.

In contrast to this, in hematite ore sinter B, the strength has a minimum at HS_{50} = 0.5 mm for the ore and 0.8 mm for the sinter charge. With an increase in the size to the value HS_{50} = 1.4 mm for ore and 1.5 mm for sinter strength, the strength increases to a maximum and then decreases again.

Both extremes of strength in both the smallest and the largest fractions are expressed equally sharply.

4.7 Reduction behavior and influence of the oxidation state

As known from the results of other studies [7], the agglomerate at a temperature close to 500 °C, in weakly reducing conditions, tends to especially strong destruction. To obtain data on the strength of the agglomerate during the reduction process, the following test was carried out: an agglomerate with a size of 12.5–16 mm in an amount of 500 g was loaded into a rotary kiln with an inner diameter of 150 mm and a length of 540 mm with an external electric heater. The speed of rotation of the furnace was 10 rpm. The oven has four 20 mm high plates. Inside the sample was heated for 40 min with a reducing gas consisting of 24 vol.% CO; 16 vol.% CO_2, and 60 vol.% N_2, up to 500 °C. The exposure at this temperature was 1 h. Then, in a stationary furnace, the sample was cooled with nitrogen to 400 °C, and then with air access. After the end of the experiment, the sample was dispersed according to the size class of +6.3 mm and –0.5 mm. The degree of agglomerate reduction was calculated from the weight loss.

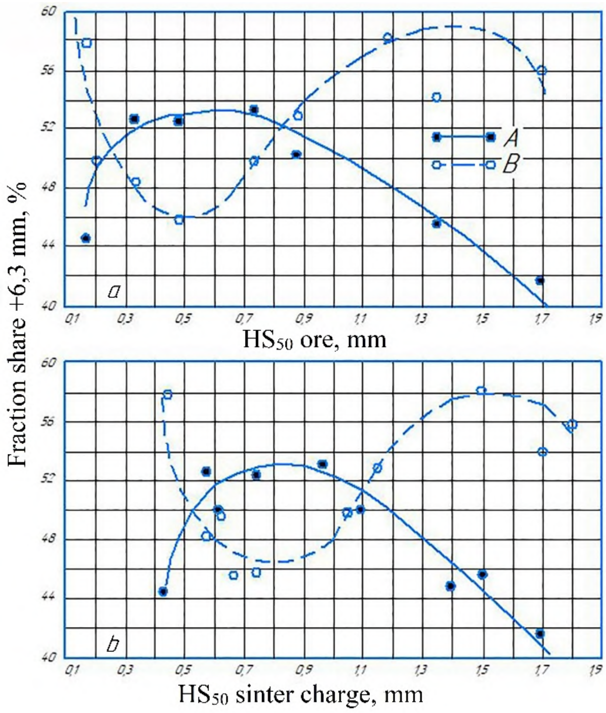

Fig. 6. Dependence of drum strength on the size of ore and sinter charge

The recovery test showed that all the resulting agglomerates under these conditions were more or less destroyed. So, for agglomerate from magnetite ore A, the residual content of +6.3 mm fractions was 0.2-5.3 wt.%, and from hematite ore B - 0.7-14.4 wt.%. These data are very unsatisfactory and are also explained by the basicity of agglomerates 1.3, at which they have a high tendency to destruction under weakly reducing conditions.

Fig. 7 shows the dependence of agglomerate abrasion on the size of the ore and sinter charge. At the same time, a decrease in abrasion is seen with an increase in the size of the ore or batch.

No differences were found between magnetite and hematite ores. The points for both ore grades are evenly spaced around the straight line. When determining the dependence of abrasion on the content of the fraction –0.1

mm, it was found that when the content of this fraction is more than 10 wt.%, the abrasion remains constant even at very unfavorable values (32 wt.%) and decreases only when the content of the fraction –0.1 mm is below 10 wt.%.

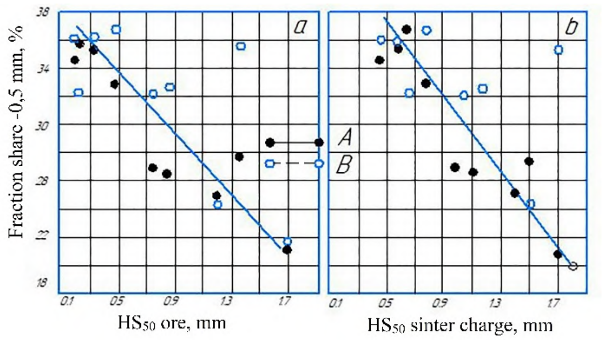

Fig. 7. Dependence of the destruction of the agglomerate at the beginning of recovery on the value of HS_{50}

As already mentioned, under these conditions, the demand for coke with an increase in size increases. However, at the same time, the FeO content in the finished agglomerate also increases. Fig. 8 it can be seen that with an increase in the FeO content, abrasion decreases. It can be assumed that this influences the improvement of abrasion with increasing particle size.

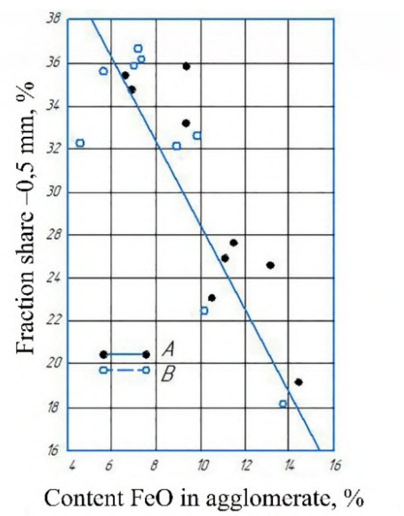

Fig. 8. Dependence of agglomerate destruction at the beginning of recovery on the FeO content

The sintering performance, as expected, clearly depends on the coke consumption. In fig. 9 clearly shows the difference in the demand for coke when using hematite and magnetite ores. To achieve the same productivity, this requirement for both ores differs by 1.5–2 kg of coke/100 kg of ore mixture.

The demand for coke also determines the FeO content or the oxidation state of the agglomerate. With the same fuel consumption, the oxidation state of sinter from hematite ore B is 2–3% higher than sinter from magnetite ore A. However, since the demand for coke for magnetite ore with the same size of sinter charge is about 1.5–2 kg lower than for hematite, the oxidation state of the finished agglomerate, as can be seen from fig. 9, with a corresponding change in the consumption of coke in both cases is the same and does not depend on the content of magnetite in the sinter batch.

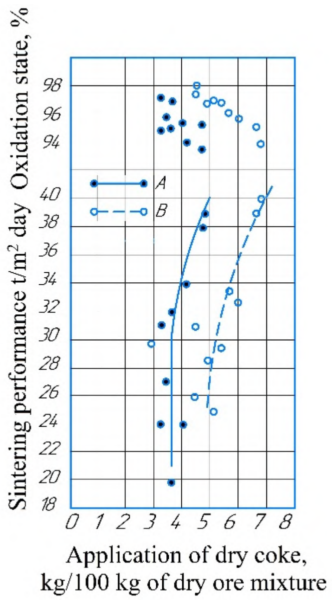

Fig. 9. Dependence of the sintering performance and the oxidation state of the agglomerate on the demand for coke

The agglomerate was tested for reducibility at a reduction temperature of 1000 °C with simultaneous loading of the sample. The amount of oxygen withdrawn was measured in wt.%/min at a reduction rate of 40%. The obtained indicators of recoverability can be considered very high. For both ores, with an increase in the grain size, a certain decrease in reducibility is noticeable. But since with an increase in particle size, the need for coke increases, and thereby the FeO content in the finished agglomerate, fig. 10 shows the dependence of the recoverability on the FeO content.

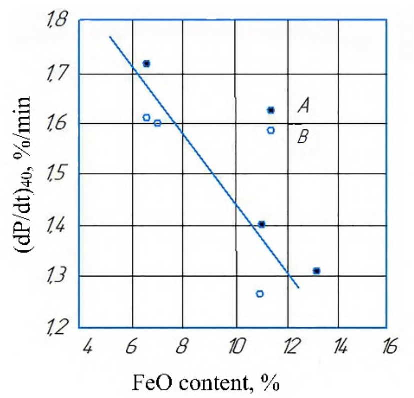

Fig. 10. Dependence of reducibility on the FeO content in the agglomerate

With an increase in the FeO content in the agglomerate, the reducibility decreases. It is also seen that the reducibility of agglomerates from magnetite and hematite ore mixtures is the same.

https://doi.org/10.1051/e3sconf/202128007012

5 Conclusions

Experiments on sintering artificially obtained mixtures of fractions from magnetite ore A and hematite ore B made it possible to reveal a number of features of this process depending on the grade and size of the ore. In particular, it can be concluded that:

- the gas permeability of the layer and the sintering productivity increase with increasing size for both ores. Only in the area of very fine fractions was there a difference between hematite and magnetite ore.

- better gas permeability and higher productivity of sintering in the area of fine fractions for hematite ore can be explained by better lumpiness of the charge due to the higher content of adhesive components;

- the minimum need for fuel was observed at an average particle size;

- the best values of the drum strength of the agglomerate were obtained with different sizes of hematite and magnetite ores, and the nature of the change in drum strength from the size differs significantly for these ores;

- a certain increase in strength charge an increase in the size of both ores or sinter mix was observed with an increase in the FeO content in the agglomerate;

- the oxidation state of the sinter at the same size and a certain predetermined consumption of coke is the same for both the hematite ore sinter and the magnetite ore sinter.

The established patterns will make it possible to optimize the granulometric composition of the sinter mixture, which will lead to an increase in the efficiency of the sintering process, namely, to a decrease in solid fuel consumption, which, in turn, will reduce the harmful effect on the environment by reducing CO_2 emissions. In addition, improving the strength of the agglomerate will reduce the formation of dusty fractions (<0.1 mm) during shipment and further transportation to the consumer.

Force index computation for a magnetic separator based on permanent magnet

Fatima Ezzahra Kassid[1,*], *Essaâdia* Azelmad[1], *Lahbib* Bousshine[1], and *Abdelmajid* Berdai[2]

[1]National Higher School of Electricity and Mechanics of Casablanca, Hassan II University, Material and Structure Mechanics Team, Casablanca, Morocco
[2]National Higher School of Electricity and Mechanics of Casablanca, Hassan II University, Electrical Systems and Energy Laboratory, Casablanca, Morocco

Abstract. Magnetic separation devices are widely used to separate tramp of iron from a specific feed of materials. Many industries rely on those devises and the variety of technological solution depend mainly on the characteristic of the tramp to be separated. In this paper, main characteristics of low intensity magnetic separation devices based on permanent magnets for dry feed are considered to evaluate force index computation.

1. Introduction

For a suspended magnetic separator based on permanent magnet, its capacity to generate enough force index and torque of rotation are essential for assessing its efficiency [1]

The torque must rotate the particle following its axe of magnetisation and the force index should attract it to the separator. Both factors depend on magnetic induction generated by the permanent magnet as it's expressed in equation (1).

$$\overrightarrow{\boldsymbol{fm}} = \boldsymbol{\nabla}(\underrightarrow{\boldsymbol{B0^2}}) \tag{1}$$

Understanding factors impacting magnetic induction flux is very essential to move forward with understanding force index mechanism. Many studies discussed explicitly those factors, like:

shape and configuration of the magnet : flat magnets produce less B than bar magnets .If magnets are put in an assembly, the produced B depends on the configuration type: attraction or repulsion. [2].this help identifying the location of the "zero force" in the separator design.

Orientation of the field: Field flux shape depends on the orientation of the magnetisation inside the magnet. Particle should be surrounded by the magnetic induction flux, in order for the force to be applied .It was proved for rectangular magnets, that orientation through their thinnest direction help increasing the produced B and give a higher energy [3]

Also, uniformity of the magnetic field should be taking seriously into consideration. If H is not uniform, the particle has to be pushed to a smaller distance, from an initial energy state to a final energy state. [4].

This paper, by means of computing method using finite element, aims to propose a program evaluating the required force index to pull the particle to the magnet, starting by magnetic induction flux calculation.

The program can be used in the design phase of the magnetic separator by choosing the optimum dimensions and precise magnet parameters. It can also be used in the final stage by simulating the behaviour of the separator towards the particle.

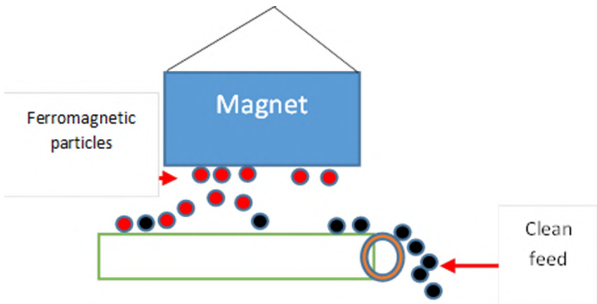

Fig. 1. Suspended magnet separator.

As vector potential method appears to be more effective method to calculate magnetic induction than scalar potential for this application [5]. This method is used in two dimensions with triangular elements. Permanent magnet is chosen as parallelepiped magnet, where its dimensions are shown in "Fig.2",:

Firstly, a mathematical formulation based on vector potential is presented, and then boundary conditions are discussed. Afterwards, finite element method is used in order to convert the obtained equation into matrixes.

Secondly, a brief presentation of the program generated by MATLAB is given in order to implement the data using the finite element method.

Thirdly, an analytical formula based on the shape of the magnet is also considered as to compare the results obtained by the finite element method and the analytical formulas.

Furthermore, three study cases are presented to evaluate and test the reliability of the program and to explore its features.

2. Theoretical background

2.1.Introduction

Magnetic field vectors can be expressed in terms of either the magnetic field strength H or the magnetic induction B[6] .the field vectors are related by:

$$\mathbf{B} = \boldsymbol{\mu}_{\mathbf{m}}.\mathbf{H} \tag{2}$$

With μ_m : the magnetic permeability constant.
In a vacuum, the permeability has the value of

$$\boldsymbol{\mu}_{\mathbf{m}} = \boldsymbol{\mu}_{\mathbf{0}} \tag{3}$$

When a magnetic field passes through a material, the material acquires an induced magnetization M given by:

$$\mathbf{H}.\boldsymbol{\chi}_{\mathbf{m}} = \mathbf{M} \tag{4}$$

Where χm the magnetic susceptibility of the material.
The magnetic induction can also be expressed as

$$\mathbf{B} = \boldsymbol{\mu}_{\mathbf{0}}.(\mathbf{H}+\mathbf{M}) \tag{5}$$

Eq (2),(4) and (5) show that

$$\boldsymbol{\mu}_{\mathbf{m}}= \boldsymbol{\mu}_{\mathbf{0}}.(1+ \boldsymbol{\chi}\mathbf{m}) \tag{6}$$

Which relates the permeability to the susceptibility.
Following Maxwell‘s equation for magnetostatic. magnetic field is expressed as follow:

$$\nabla\mathbf{x}\mathbf{H}=\mathbf{J} \tag{7}$$
$$\nabla.\mathbf{B}=\mathbf{0} \tag{8}$$

Where j is the density charge.
Via a magnetic vector potential approach. The flux density may be written in terms of the vector potential A as:

$$\mathbf{B}\mathbf{x}\nabla = \mathbf{A} \tag{9}$$

Where A is the vector potential
By using Lorentz gauge, the Alembert equation was found as follow:

$$\mu\mathbf{J} = \Delta\mathbf{A} - \mu\frac{\varepsilon\partial^2 A}{\partial t^2} \tag{10}$$

In quasistaionary terms:

$$\mu\mathbf{J} = \Delta\mathbf{A} \tag{11}$$

And finally, vector potential is expressed via Poisson's equation formulation

2.2.Boundary conditions

The permanent magnet is a suspended one in the air, its flux lines are parallel to the boundary edge. Hence the Dirichlet conditions are the best to express this problem.
A = 0 at the boundary of the space of study of the permanent magnet

3. Finite element formulation

3.1.Introduction

The boundary value problem under consideration is defined by the second order PDE:

$$\boldsymbol{\mu}\mathbf{J}=\Delta\mathbf{A} \tag{12}$$

3.2.Domaine discretization

Triangular elements are used in this case, with the following interpolation equation:

$$\emptyset^{\mathbf{e}}(x,y) = \sum_{\mathbf{j=1}}^{\mathbf{3}} \mathbf{N}_{\mathbf{j}}^{\mathbf{e}}(x,y)\emptyset_{\mathbf{j}}^{\mathbf{e}} \tag{13}$$

By using variation formulation, we get the expressions of the matrices

3.3.Final formulation

Set of matrices are represented as follow:

$$\mathbf{K}_{i,j}^{\mathbf{e}} = \int\left(\left(\frac{\boldsymbol{\alpha}\mathbf{d}N_i^e}{\mathbf{d}x}\frac{\mathbf{d}N_j^e}{\mathbf{d}x}\right) + \boldsymbol{\beta}\mathbf{N}_{\mathbf{i}}^{\mathbf{e}}\mathbf{N}_{\mathbf{j}}^{\mathbf{e}}\right)\mathbf{d}x \tag{14}$$
$$\mathbf{b}_{\mathbf{i}}^{\mathbf{e}} = \int \mathbf{N}_{\mathbf{i}}^{\mathbf{e}}\mathbf{f}\mathbf{d}\mathrm{x} \tag{15}$$
$$\mathbf{g}_{\mathbf{i}}^{\mathbf{e}} = \boldsymbol{\alpha}\mathbf{N}_{\mathbf{i}}^{\mathbf{e}}\mathbf{d}\emptyset/\mathbf{d}x \tag{16}$$
$$(\emptyset^{\mathbf{e}}) = \begin{pmatrix}\emptyset_{\mathbf{1}}^{\mathbf{e}}\\ \emptyset_{\mathbf{2}}^{\mathbf{e}}\end{pmatrix} \tag{17}$$
$$(\mathbf{K})(\emptyset) = (\mathbf{b}) + (\mathbf{g}) \tag{18}$$

4. Finite element program

4.1.Introduction

For its simplicity and reliability of results, MATLAB is used to program the finite element formulation of matrixes.
The basic structure of this program is split to many sections.
Global declaration section: where the model is presented, characteristic of the environment, magnet and particle are defined like number of elements, nodes, magnetic induction, type of elements. This section can be updated with each specific study case.

Main function: this section is considered the heart of the program. It includes all equations and formulas related to calculating all necessary parameters.

Sub-program function: this section is only optional as it can be included in the Main function section. On the other hand, it's considered essential to create a clean and a visible program. Especially if type of elements and dimensions changed (ex: quadratic instead of triangular). It includes all sub-functions required to calculate the final equation like: Stiffens matrix and source matrix.

Results view section: in this suction, graphs, tables and curves can be obtained to visualise the output of the program.

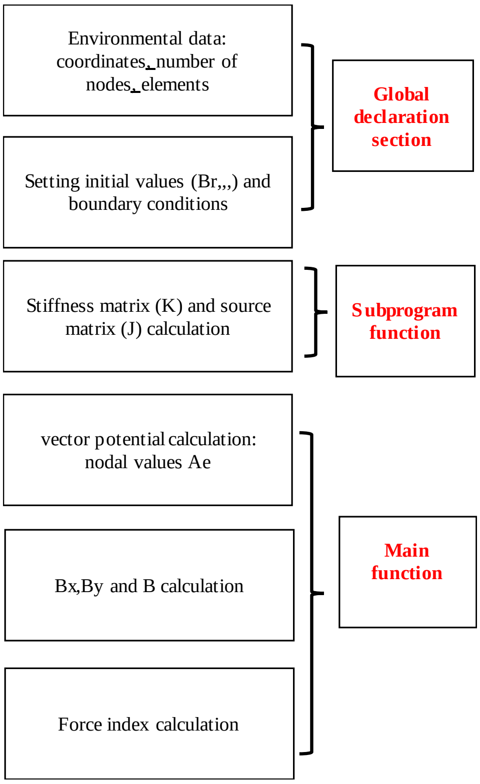

Fig. 2. Main sections of MATLAB program.

4.2.Magnetic induction Formulation

Fig below "2" describes set of steps related to the main sections of the program as discussed above.

Following steps mentioned below allow to calculate the nodal values of force index in each node. In case where global force index is desired, vector potential and magnetic induction values should be calculated for each element, to allow creating a global matrix structure for magnetic induction and it's gradient.

5. Analytical model

5.1. Introduction

Several previous publications had already discussed the behaviour of magnetic field of a rectangular permanent magnet. Elaboration of mathematical formulation depends mainly on type of model (spring model, charge model….) and number of dimensions (two or three) [6, 7, 8].

In this work, the charge model method is taken into consideration as a reference to compare the obtained results. According to this model, magnet is considered as a set of distribution of equivalent "magnetic charge" [8].

Expressions are presented in three dimensions, nevertheless they will be customized to fit two dimensions model.

Considering magnet having two surfaces, expressions of the magnetic induction will be separated based on top (Z=0) and the bottom (Z=L).

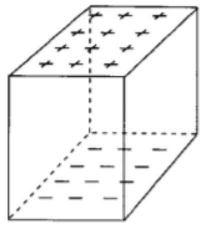

Fig. 3. Rectangular magnet: equivalent Charge model.

5.2.Formulation

For the top surface of the magnet (z=0), B(Z) is:

$$\mathbf{B_z}(z) = (\boldsymbol{\mu_0} * \mathbf{M_s}/\boldsymbol{\pi}) * [\frac{\pi}{2} - \frac{\tan^{-1} z * \sqrt[2]{a^2+b^2+z^2}}{a*b}) \quad (19)$$

For the bottom of the magnet (Z=L),B(Z) is:

$$\mathbf{B_z}(\mathbf{z}) = (\boldsymbol{\mu_0} * \mathbf{M_s}/\boldsymbol{\pi}) * [\frac{\tan^{-1}(z+l) * \sqrt[2]{a^2+b^2+z(z+l)^2}}{\mathbf{a*b}} - \frac{\tan^{-1} z * \sqrt[2]{a^2+b^2+z^2}}{a*b}) \quad (20)$$

a and b are the length and the width of the magnet
Z is the distance between the magnet and the particle.
Ms: Magnetization of the magnet

6. Simulation and computing

6.1.Case 1:comparing the magnetic potential

6.1.1. Introduction

To create a model of the permanent magnet. FEMM was used with the following data:

2a = 2 mm
2b = 2mm
L = 1 mm
Br = 1.4T according to Y.

Both Femm [9] and Marc were used to compute the magnet, yet only Marc's results were taken into consideration, as it allows more precision and variation of results based on the orientation of the magnetization.

https://doi.org/10.1051/e3sconf/202128007013

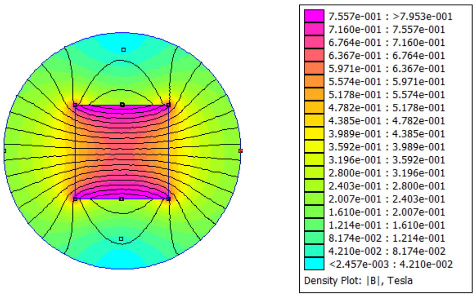

Fig. 4. Computation of magnetic induction flux -Femm.

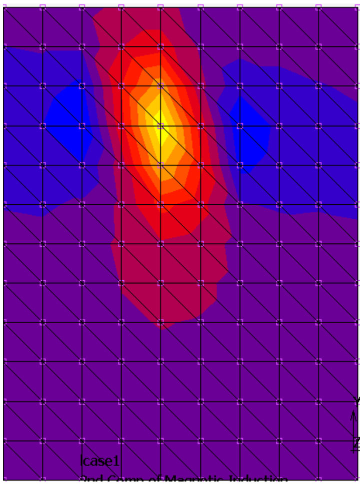

Fig. 5. Computation of magnetic induction flux -MARC.

6.1.2. Results

Fig 4 and 5 visualize flux lines of the magnet. As it can be seen, flux lines tend to reach the terminal and the pole spacing.

Fig. 6 shows the results of the variation of nodal magnetic vector potential obtained by the Marc and MATLAB methods for 36 nodes. As it can be seen, the difference between the two curves is hardly perceptible, because the estimated margin of error for Marc is less than 3%. As stated in its official publication [10] and it can therefore be considered identical to the results given by MATLAB.

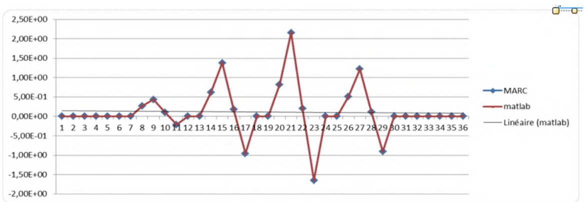

Fig. 6. Values of vector potential for 36 nodes. Node 21 present the maximum value of vector potential, afterword's the values start decreasing.

The table below N "1" helps understanding variation of values of vector potential generated by the magnet following Y direction.

Nodes are taking following Y direction. It is clear that as the distance from the magnet increases, the values of the potential vector drop decrease.

As the magnetic vector potential can be interpreted as potential energy per unit element of current, so direction of vector potential will determine the needed energy required by magnet to create an attraction force with the particle (fig 7)

Table 1. Values of potential vector.

NODE	MARC	MATLAB
19	2,05E-10	0
20	0,821356	0,8214
21	2,15875	2,1588

As it can see in "fig 6 and 7", the difference between both results is hardly perceptible. Error margin is less than 6%, this part of the program can be considered validated.

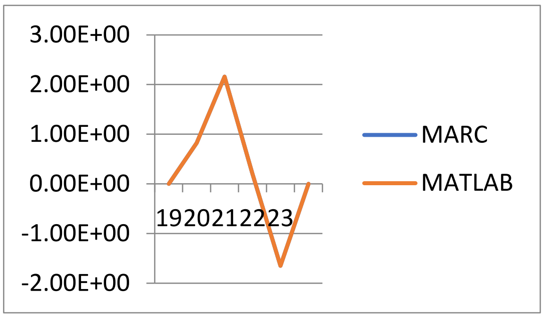

Fig. 7. Variation of vector potential.

6.2.Case 2: comparing magnetic induction

For this case, same data as the first example will be used to calculate the external magnetic induction generated by the magnet.

Table below "2" illustrate values of magnetic induction starting from the outer surface of the magnet to the location of the particle.

The analogy between values of vector potential and magnetic induction is very similar. Once Again, the more the distance from the magnet increases, the more the magnetic induction values decrease.

To validate the programme, an analytical calculation has been developed. Figure 8 shows that the values can be considered almost identical for the first two values, which is logical given the change of medium between the magnet and the air.

Table 2. Variation of magnetic induction.

No	B(Z) Analytical model (T)	B(Z) by Matlab (T)
0.0000	0.1470	0.15170
1.0000	0.0693	0.07146
2.0000	0.0298	0.03073
3.0000	0.0141	0.01451
4.0000	0.0071	0.00730
5.0000	0.0037	0.00380
6.0000	0.0019	0.00190
7.0000	0.0008	0.00080
8.0000	0.0003	0.00029

 https://doi.org/10.1051/e3sconf/202128007013

The understanding of the behaviour of magnetic induction outside the magnet is a major factor in the choice of magnet material. This means that each magnet has a unique internal energy and induction field range.

6.3.Case 3: distance choice between particle feeds and magnet based on force index.

Following this case, impact of burden on force induction will be explored. Likewise, same data will be taken into consideration .As for the particle data:

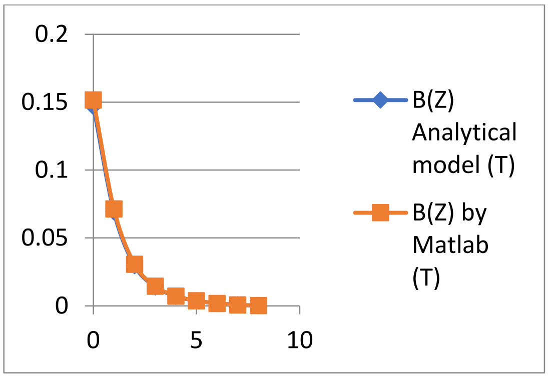

Fig. 8 Variation of magnetic induction.

- µp=1000
- ϱP= 7800 Kg/M^3
- Pb= 800 Kg/M^3
- Φ= 10 mm
- N= 0,33
- G=9,8
- µ0= 4∏ 10^(-7)

In general, “burden” is a material with a different permeability covering the ferromagnetic particle required to be separated (figure 9).

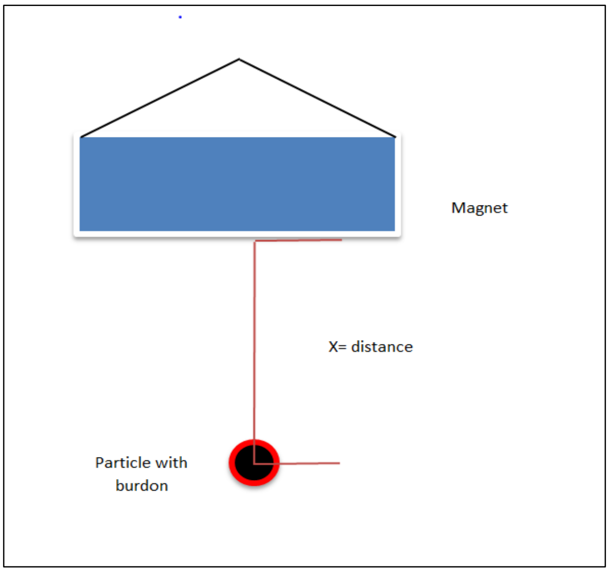

Fig. 9. Separation with burden.

Force index required to achieve the separation is:

- without burden : fm= 0,0318 T^2/m
- with burden : fm= 0,0374 T^2/m

As it can be seen, force index required to attract a particle covered by burden is more important than the value required for a particle alone.

SvoBoda in his work [1], explained explicitly the impact of the burden on the required force index depending on the dimensions of the burden. Force index increases steeply with increasing depth of the burden .

He stated also that force index depends solely on the shape of the particle size and not on its geometry, like it’s the case with the magnetic force.

Therefore, this factor must be taken seriously during the separator design process to get precise data.

By considering results of magnetic induction in case 2, the optimum distance between the magnet and the particle feed should me 1 mm to achieve a field gradient superior than 0,037^2 required to achieve the value of force index.

The further we get from the magnet, the more force index is required to achieve the separation process. Consequently, the bigger the magnet dimensions should be.

When dealing with real process, it is essential to take into consideration the distance between the suspended magnet and the conveyor band including the feed as one of the main factor for the magnetic separator choice to get the optimum design.

7. Conclusion

A finite element program for calculation of the force index is presented. Numerical simulation of the vector potential, magnetic induction and force index have been carried out in 2D Cartesian form.

This program can be used for modelling the permanent suspended magnetic separation and analyse the behaviour of different flux.As it was shown in case 1 and 2.

It can also be used to assist in the design phase of the separator to obtain optimal dimensions while simulating its force index behaviour towards the magnetised particle under different circumstances as it was shown in case 3.

Given the impact of the burden surrounding the particle on the required force index, as it was shown in case 3, most of separator designers, take into consideration this factor .As the force index required increases depending on the burden’s volume.

The logic to elaborate the force index has been presented following the different stages of the program. Starting with the vector potential and ending with the calculation of the induction field gradient.

The program allows to communicate the results of each step of the simulation and to compare them with the analytical results as presented above (cases 1-3).

The results showed that the estimated error between computed and analytical values is between 3% and 6 %

In addition to all the features of this program, it can Also interact with different platforms to allow calculus for large numbers of nodes (ex 13000 Nodes).

Furthermore, duo to its subprogram function section, the program allows a quick switch to a different type of elements and give the possibility to compare results for each simulation.

It worth mentioning also that although the used approach has been applied to a rectangular magnet, it's equally applicable to the analysis of the magnetic field and force index a calculation of a cylindrical magnet, by taking into account the correct formulas.

This allows for the program to cover more types of magnetic separators and to help better understanding the real process of separation.

Plant secondary metabolites as bioactive substances for innovative biotechnologies

Anastasiia Revutska[1], *Victoriya* Belava[1], *Anastasiia* Golubenko[1], *Nataliya* Taran[1], and *Minglei* Chen[1]

[1]Taras Shevchenko National University of Kyiv, ESC «Institute of Biology and Medicine», 64/13 Volodymyrska Str., Kyiv, 01601, Ukraine

Abstract. Plants are natural sources of bioactive compounds, and the intensive use of wild plants to obtain them, in particular secondary metabolites, depletes natural biocenoses. Instead, modern biotechnological methods, especially cell and tissue culture in vitro, make it possible to get environmentally friendly, highly productive plant raw materials that are able to synthesize and accumulate specialized substances, which are valuable for pharmacology, cosmetology, and medicine. Regenerating in vitro-plants of different plant species such as Acorus calamus L., Phalaenopsis sp. were obtained in our research. It was proved that by changing the cultivation conditions it is possible to change the content of substances of secondary metabolites in explants and in the nutrient medium under aseptic culture.

1 Introduction

Constant changes in environmental conditions necessitate changes in the biochemical and physiological processes of all living organisms in order to increase their adaptive capacity. Numerous mechanisms of adaptation to the action of abiotic, biotic and anthropogenic factors specify unique properties of plants. Plants synthesize hundreds of thousands of organic compounds, which are divided into three main groups. The first group includes primary metabolites − compounds that are directly required for plant growth. The second one − phytohormones, which perform a regulatory function in the plant body and metabolism in general. To the third group, scientists attribute organic substances with relatively low molecular and high biological activity, namely substances of specialized metabolism. The other name for this group of substances is secondary metabolites [1, 2].

As early as the XX-th century, Nobel laureate in physiology and medicine, Albrecht Kossel firstly introduced the term «secondary metabolite», and Chapek described this kind type of substances as the final products of metabolism. Further development of science − the emergence of new research methods in molecular biology, biochemistry, physiology helped to establish that secondary metabolites play several roles in the growth and development of the plant organism, and are also synthesized in response to various stressors [3].

Plant tissues and organs synthesized a huge variety of compounds of secondary origin. Primary metabolites are formed in the cells of all plant species, but specialized substances may be unique to individual species. The plant usually synthesizes a complex of such substances, the individual components of which have an additional and enhancing effect on more than one molecular target. Secondary metabolism originates from different primary pathways, which indicates changes in the activity of enzymes of main metabolism during evolution. As a result of such changes, completely new compounds were formed that increased the plant resistance to the factors of a certain environment and the gradual transformation of primary compounds into specialized metabolites [4].

Scientists classify secondary metabolites by type of their chemical structure into the following classes:

- alkaloids;
- isoprenoids;
- saponins;
- glycosides;
- phenolic compounds etc.

Each of these groups includes from units to several hundred or thousands of individual compounds. Their chemical structure determines the specificity of the functions of such substances. For example, plants can synthesize secondary metabolites to protect itself against various pathogens (viruses, bacteria, fungi, etc.) or to neutralize toxic products of primary metabolism. Interestingly, some secondary compounds largely determine the nutritional and taste qualities of various plant products. All the plants' properties for the formation of multifunctional organic compounds with various properties helps to produse body care products, immune support, a great use in medicine (for example, as analgesics, antioxidants, blood pressure normalizers, etc.), use as food supplements, bioindications, and other [5,6].

1.1 Plant phenolic compounds

Phenolic compounds are included to one of the most diverse and numerous classes of secondary metabolites of the aromatic series, characterized by the presence of a benzene ring consisting of six Carbon atoms (C_6); and one or more hydroxyl groups (OH). The classification of phenols is based on determining the number of Carbon atoms and aromatic rings in molecules (from one or two benzene rings to many – polyphenols). Depending on the chemical structure and properties are distinguished [7]:

- simple phenols;
- coumarins;
- tannins;
- flavonoids;
- xanthones;
- chromones;
- stilbenes;
- lignans.

In the plant body, the phenolic substances synthesis occurs with the involvement of enzymes of the three main ways of transformation of aminoacid phenylalanine:

- polyketide pathway (elongated side chains of phenylpropanoids, flavonoids are formed ($C_6 - C_3 - C_6$);
- shikimatic pathway (synthesis of phenyl-propanoid derivatives ($C_6 - C_3$));
- acetate-mevalonate pathway (formation of aromatic terpenoids, in particular monoterpenes).

Natural phenols are synthesized and accumulated in all plant organs, for example in members of the *Orchidaceae*, *Theaceae*, *Gentianaceae* and other families, the content of which is 2-3% of the total mass of organic matter of plants, in some cases can reach 10% or more. These compounds have a strong effect on plant growth, elongation of stems and roots, inhibiting seed germination, play an important role in wound healing, cell division [8,9].

Phenolic compounds determine the color of leaves, flowers, fruits. They are also involved in the growth and reproduction of plants involved in the mechanisms of protection against ultraviolet radiation (UV-light), infection with pathogenic microorganisms, parasites or from being eaten by animals, and so on. Phenolic substances are synthesized when the plant cell receptors recognize potential pathogens by preserved pathogenic-associated molecular features, which leads to a response to a biological stimulus. Therefore, the development of infection is limited long before the spread of the pathogen throughout the body. They are also part of plant foods and beverages, such as vegetables, fruits, cereals, legumes, chocolate, tea, coffee and others. In addition, phenolic compounds determine the healing properties of plants, making them extremely valuable for cosmetology, pharmacology and medicine. The study of the content of certain phenols gives grounds to distinguish between plant species, i.e. to use as a marker for molecular taxonomy [10].

1.2 Sources of xanthones phenolic compounds

Xanthones are heterocyclic compounds belonging to secondary metabolites, namely polyphenolic substances with the molecular formula $C_{13}H_8O_2$. Xanthones have been studied since the early 1900's and it has been established that the natural sources of these compounds are plants, as well as fungi, lichens and even bacteria.

The classification of these polyphenols is based on the number of benzene rings, as well as the type, number and position of substituents. The biosynthesis of plant xanthones occurs by converting shikimic acid with the formation of aromatic rings, and acetate – in the pirone ring. These substances are derivatives of diphenylketone and the simplest formula of the xanthone molecule has the form (Fig. 1) [11,12].

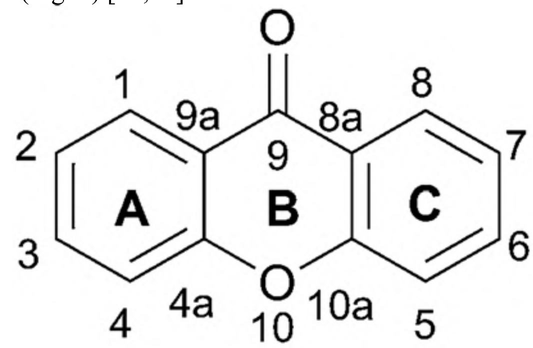

Fig. 1. Formula of xanthone with numbers of Carbon atoms

Xanthones isolated from natural sources are classified into 6 main groups:

- simple xanthones;
- xanthone glycosides;
- prenylated xanthones,
- xanthanolignoids;
- bixanthones;
- mixed xanthones.

From ancient times to the present days, people use plants in folk and conservative medicine as a source of bioactive substances for the prevention and treatment of various diseases. It has been experimentally proven that these secondary metabolites act as lipid peroxidation inhibitors, metal chelators, free radical scavengers, ie as antioxidants. Thus carry out hepatoprotective, anti-inflammatory action and prevent the development of cancerous tumors. As for the representatives of phenolic compounds, xanthones are characterized by other medicinal properties, namely: antiviral, antibacterial, antifungal, etc. [13,14].

Especially well-known plant sources of these polyphenols are representatives of the following plant families: *Moraceae*, *Polygalaceae*, *Gentianaceae*, *Hypericaceae*, *Iridaceae*, *Asparagaceae* and others. That is why these plants are very valuable for the pharmaceutical industry and there is a need for alternative methods of obtaining plant raw materials with advanced modern biotechnological measures [15-18].

1.3 Sources of flavonoids phenolic compounds

Flavonoids are another group of polyphenolic compounds that have the general formula $C_6 - C_3 - C_6$. They are also classified by the number of benzene rings and the type of substitution into the following main groups:

- halcones;
- catechins;

- flavonols;
- flavonones;
- anthocyanins;
- isoflavones;
- proanthocyanidins.

Natural flavonoid sources are algae, mosses, horsetails, ferns, as well as gymnosperms and angiosperms. Among the angiosperms representatives are the families *Lamiaceae*, *Rosaceae*, *Fabaceae* and others can be mentioned, which synthesize flavonoids different in structure and properties. Flavonoids are accumulated in leaves, roots, fruits, seeds of plants. Like other phenolic compounds, they are derivatives of phenylalanine and malonyl-CoA. One molecule of flavonoid compound consists of two phenyl residues A and B combined with a propane link, which can close in an oxygen-containing heterocycle C (Fig. 2) [19-21].

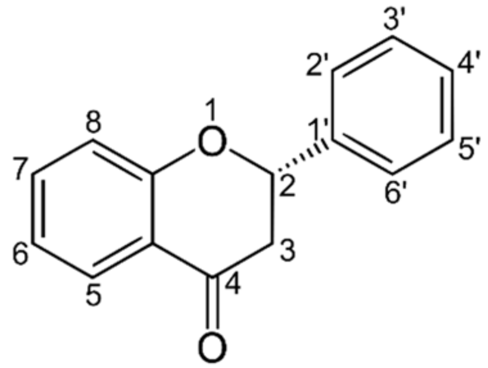

Fig. 2. Formula of flavonoid with numbers of Carbon atoms.

Flavonoids are plant pigments that also play an important role in increasing the plant resistance to stress factors. In addition, they help determine the quality of food, acting as preservatives and have strong antioxidant, anti-inflammatory, antimutagenic and anticancer properties. These polyphenols can modulate key functions of cellular enzymes. Due to these properties, plants containing flavonoids are also used in the manufacture of medicaments, as well as nutraceutical, pharmaceutical, medical and cosmetic applications [22,23].

1.4 Biotechnological importance of secondary metabolites of plants

Due to the increased need in the use of unique in structure and properties of substances of specialized synthesis, the volume of extraction of plants-sources of secondary metabolites from natural sites is increasing, resulting in reduced biodiversity of natural phytocenoses. It also leads to a decrease in the number of individual plant species, which are becoming rare and some even endangered. Instead, the development of plant biotechnology allows it to be used as a raw material for the extraction of valuable compounds not only from wild or artificially grown plants, but also from microclonal propagation and culture of plant cells, tissues and organs *in vitro*. The use of these cultivation methods opens up the possibility of regulated synthesis of bioactive secondary metabolites, genetic transformation in order to obtain more productive regenerating plants, while preserving their natural sources. Regulation of the formation of valuable substances is carried out by selecting the composition of nutrient media, lighting, temperature under which plants are cultivated [24].

Growing plants in controlled conditions on artificial nutrient media allows to obtain plant biomass in almost unlimited quantities, which is actually used as a source of valuable metabolites. Plant raw materials obtained in this way are environmentally friendly, not contaminated with chemical fertilizers, pesticides, herbicides, radioactive isotopes, heavy metals and the like. The use of cell cultures and painstaking selection work made it possible to get a wide range of bioactive substances (xanthones, terpenoids, alkaloids, glycosides, etc.) of plant origin both on a laboratory and industrial scale. Examples of applications of this technology are:

- cloning of plants;
- obtaining cell cultures of different types (meristem culture, callus production);
- cultivation of individual plant organs (lateral or apical buds, anthers, «hairy roots»);
- suspension cultures;
- bioreactors, etc.

The intensity of the process of formation of bioactive metabolites *in vitro* is influenced by: plant growth regulators; mineral composition of the nutrient medium; carbohydrate nutrition of explants; physical factors, such as light intensity and wavelength, artificial selection of producer cells. Thus obtained bioactive substances are widely used in pharmacological, medical, food, cosmetic and other industries for the production of goods to improve the quality of life and treatment [25,26].

That is why the aim of our research was to study different species of plants grown under aseptic conditions, callus production, as well as the use of nutrient media as additional environmentally friendly sources of pharmacologically valuable secondary metabolites. Growing plants in controlled conditions on artificial nutrient media allows to obtain plant biomass in almost unlimited quantities, which is actually used as a source of valuable metabolites.

2 Materials and methods

Cultivation material was obtained by different plant species microclonal propagation under aseptic culture conditions. Then cloned plants were grown *in vitro* for 3-5 months at 24 °C, 16-hour photoperiod on a modified agar nutrient medium Murassige-Skuga [27]. The chemical composition of the used nutrient medium:

- standart Murazige-Skuga nutrient medium (mix of micro- and macroelements) (Sigma, Germany);
- mesoinozit (China);
- composition of vitamins (LLC UKRCHIMEXPO, Ukraine): B_1 (thiamine), B_6 (pyridoxine), C (ascorbic acid), PP (nicotinic acid);
- Fe_2SO_4 (LLC «UKRCHIMEXPO», Ukraine);
- sucrose (LLC «UKRCHIMEXPO», Ukraine);
- agar (Spain);
- composition of plant growth regulators (Sigma, Germany): indolyl acetic acid, kinetin;

- casein hydrolyzate (Sigma, Germany) and yeast extract (LLC «UKRCHIMEXPO», Ukraine) were added to the nutrient medium prepeared fot *Phalaenopsis sp*.

The agar medium was also used as a source of bioactive substances. *In vitro* cultivation of plants was carried out in the research laboratory «Introduced and natural phytodiversity» of O. V. Fomin Botanical Garden of Taras Shevchenko National University of Kyiv.

Plant material and nutrient medium were quantitatively analyzed according to generally accepted methods: 96% ethanol solution was used for extraction and spectrophotometric analysis of phenolic compounds. Determination of the total content of phenolic compounds was performed using Folin-Chekolte reagent [28, 29], and the content of flavonoids − 0.2% solution of nitrate crystal hydrate of zirconyl chloride (IV) and rutin as a standard (with modifications) [30].

The content of xanthones determined chromatographically with UV-light identification of spots (at λ = 200-400 nm) by our own modification. According to the literature, the extraction of xanthones from plant material involves the use of solutions of toxic polar solvents of high concentration (70-96%): methanol, hexane, chloroform, butanol, ethylacetate or their different mixtures with 96% ethanol [31-33]. Hence, the presence of such solvents requires pre-purification of the extracts for further use in the analysis. Our modifications of the xanthone extraction method concerned the replacement of such a kind of solvents with environmentally friendly ethanol (DKP Pharmaceutical Factory LLC, Ukraine) only: 70% solution − for the extraction and 60% solution − for spectrophotometric analysis of xanthone content.

The approbation of methods covered in the literature, we noticed that repeated filtration (3-4 times) of extracts [34] instead of increasing the accuracy of the analysis, led to significant losses of the amount of test solution, which was absorbed by the filter components and it was difficult to drain the sediment. Accordingly, we noticed a negative effect on the accuracy of quantitative analysis. For that reason, we changed the extracton to one stage of 3 hours duration. The chromatographic analysis involved the use of 40% acetic acid (LLC «UKRCHIMEXPO», Ukraine) − as a mobile phase for separation the xanthones from other phenolic compounds.

The secondary metabolites content analisis in the nuriant medium is insufficiently mentioned in scientific papers only in liquid and suspension cultural medium but not in agar medium [35]. Therefore, we extracted secondary metabolites from agar medium by our own method using a low temperature staining a 70% ethanol solution, followed by centrifugation to remove rasidual particles of the agar medium [36]. The secondary metabolites content analisis of the medium was done by the same method as for the *in vitro*-plants. All extracts from plant material and nutrient medium were analyzed spectrophotometrically (SF SHIMADZU UV – 1800, Japan).

Biochemical analysis of plant material and samples of nutrient medium was carried out in the laboratory «Physiological basis of plant productivity» of the Department of Plant Biology at the Educational-Scientific Center «Institute of Biology and Medicine» of Taras Taras Shevchenko National University of Kyiv.

Our experiment was performed in triplicate, results − statistically processed according to conventional methods using the standard program Microsoft Office Excel. In preparing, the method analyzed the average data obtained, the differences between which considered significant by Student's criterion (at $P \leq 0.05$).

3 Results and discussion

As a sourse of bioactive compounds, we used different types of plants. The explants of plants of the families *Orchidaceae* (Fig. 3a) [37] and *Acoraceae* (source plant material belonged to different localities formed in 2 groups for the experiment) (Fig. 3b) were obtained [38].

a)

b)

Fig. 3. *In vitro*-regenerated plants of *Phalaenopsis sp.* (a) and *Acorus calamus* L. (b)

Quantitative analysis of secondary metabolites content (total phenolic content) showed a steady increase in the content of phenolic in the nutrient medium used for cultivation of *Acorus calamus* L. (by around 30 %) (Fig. 4).

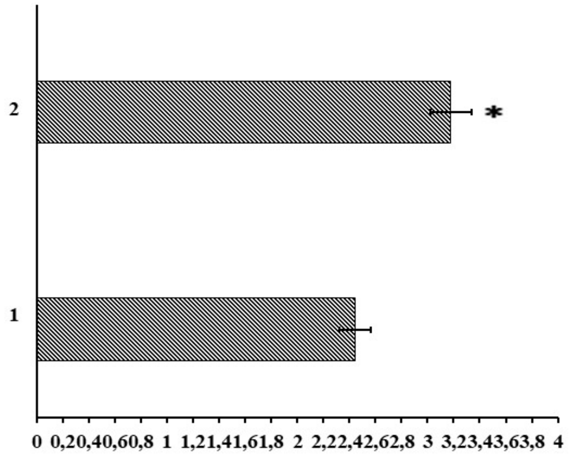
It was also described the differences in phenolic compounds content in explants of the same plant during the experiment: increasing by 2 times in explants of Group 1 in leaves and roots (Fig. 5a) and of Group 2 − only in leaves (Fig. 5b).

The obtained data on the flavonoid content in explants of *A. calamus* indicate a changing of their concentration during the experiment and aslo depending on the part of the explants: decreased in explants of Group 1 (Fig. 6), increased in explants of Group 2 (Fig. 7).

We also identified variations in chemical composition xanthones depending on the type of the explant. As an example, *A. calamus* explants of both groups syntesized and accumulated only one type of xanthones – swerchirin. There were also differences in xanthone content among the explants of two different localitets of *A. calamus.*

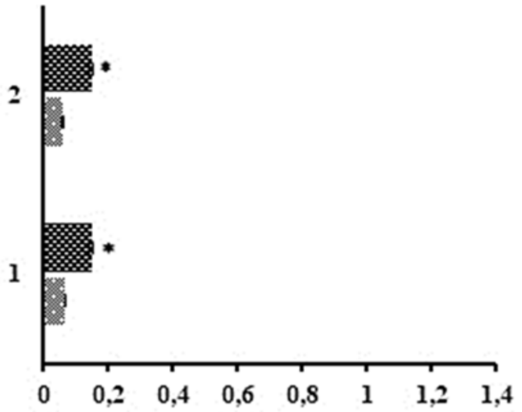
 https://doi.org/10.1051/e3sconf/202128007014

Group 1 of explants accumulated compounds in leaves and roots (Fig. 8).

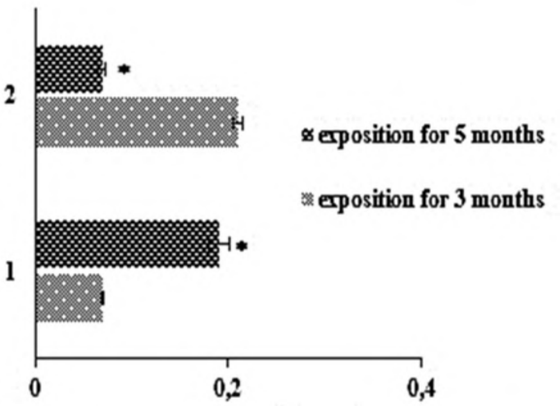


Content of phenolic compounds, mg/g

Fig. 4. Content of phenolic compounds in the nutrient medium used for cultivation of *A. calamus*, mg/g by DMW (significant at P ≤ 0,05): 1) exposition for 3 months, 2) exposition for 5 months.



a) **Content of phenolic compounds, mg/g**



b) **Content of phenolic compounds, mg/g**

Fig. 5. Content of phenolic compounds in explants of *A. calamus* L., mg/g by DMW (significant at P ≤ 0,05): a) Group 1, b) Group2, 1) in leaves, 2) in roots

However, explants of Group 2 acumulated swerchirin only in leaves and lost the starting amount of these compound in roots (almost by 50%) during the experiment (Fig. 9).

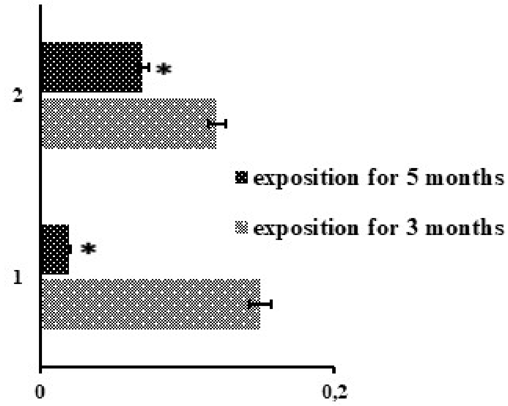


Fig. 6. Content flavonoids in explants of *A. calamus* L. (Group 1), mg/g by DMW (significant at P ≤ 0,05): 1) in leaves, 2) in roots

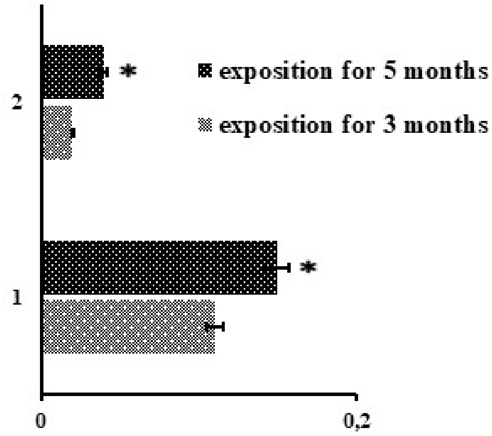

Fig. 7. Content flavonoids in explants of *A. calamus* L. (Group 2), mg/g by DMW (significant at P ≤ 0,05): 1) in leaves, 2) in roots

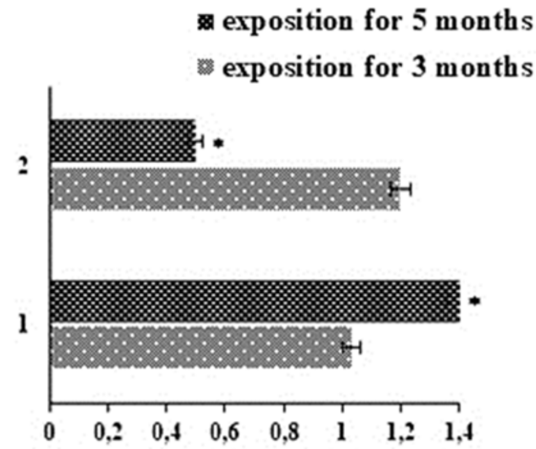

Content of swerchirin, %

Fig. 8. Content of swerchirin in explants of *A. calamus* (Group 1), % by RMW (significant at P ≤ 0,05): 1) in leaves, 2) in roots

The amount of xanthones in the nutrient medium decreased significantly over the same period of time, and the content of flavonoids was too low to be detected by a quantative analysis We also identified a different composition of xanthones depending on localities of explants that were cultivated on this medium (Fig. 10 and Fig. 11).

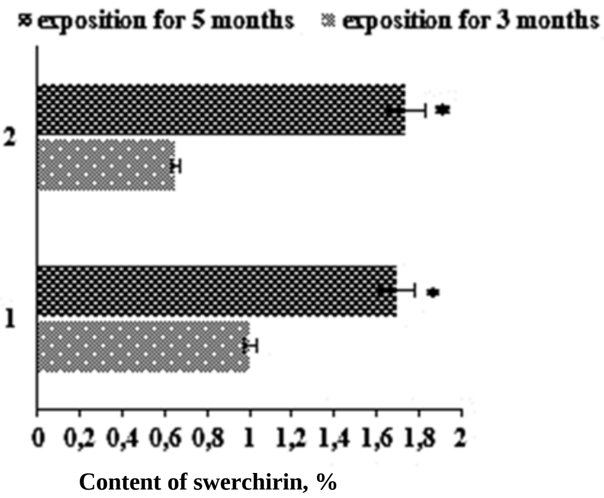

Fig. 9. Content of swerchirin in explants of *A. calamus* (Group 2), % by RMW (significant at P ≤ 0,05): 1) in leaves, 2) in roots

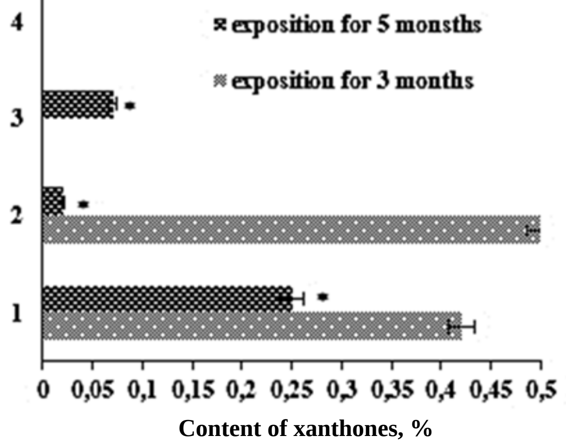

Fig. 10. Content of xanthones in the nutrient medium used for cultivation of *A. calamus* (Group 1), % by RMW (significant at P ≤ 0,05): 1) 1-hydroxy-2,3,5-trimethoxyxanthone, 2) mangostenone A, 4) swerchirin

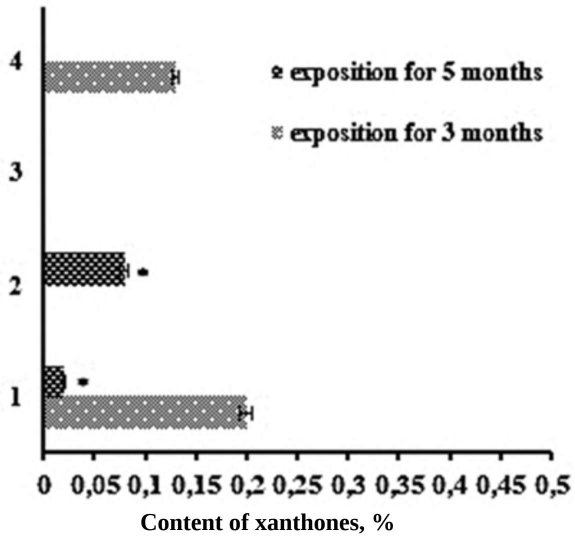

Fig. 11. Content of xanthones in the nutrient medium used for cultivation of *A. calamus* (Group 2), % by RMW (significant at P ≤ 0,05): 1) 1-hydroxy-2,3,5-trimethoxyxanthone, 2) mangostenone A, 4) swerchirin

In contrast, *Phalaenopsis sp*. explants contained different xanthones: 1-hydroxy-2,3,5-trimethoxyxanthone, decussatin, swertiaperennin, swerchirin, α-mangostin (Fig. 12).

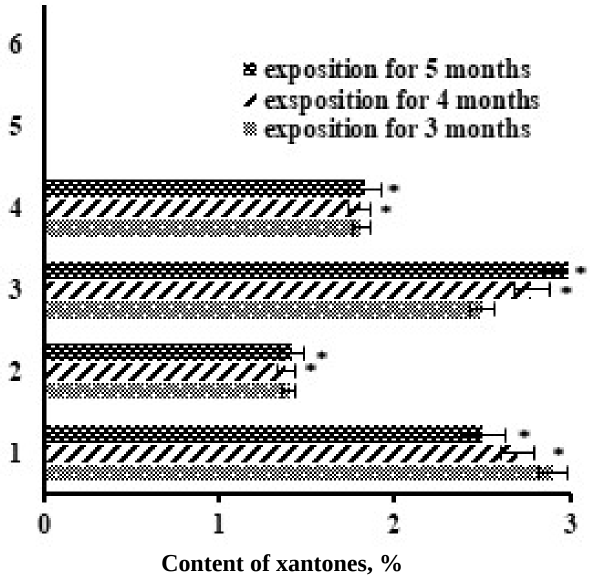

Fig. 12. Content of xanthones in explants of *Plalenopsis sp.*, % by RMW (significant at P ≤ 0,05): 1) 1-hydroxy-2,3,5-trimethoxyxanthone, 2) decussatin, 3) swertiaperennin, 4) α-mangostin 5) mangostenone A, 6) swerchirin.

The nutrient medium used for cultivation of *Plalenopsis sp.* explants contained decusatin, α-mangostin, mangostenone A and swerchirin (Fig. 13).

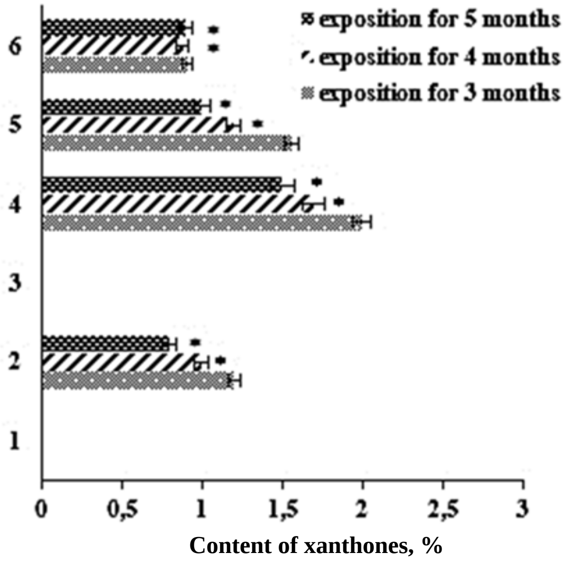

Fig. 13. Content of xanthones in the nutrient medium used for cultivation of *Plalenopsis sp.* explants, % by RMW (significant at P ≤ 0,05): 1) 1-hydroxy-2,3,5-trimethoxyxanthone, 2) decussatin, 3) swertiaperennin, 4) α-mangostin 5) mangostenone A, 6) swerchirin

All plants grew under the same conditions, so we assume that the differences in the metabolites content could be caused by genetical factors that influenced

https://doi.org/10.1051/e3sconf/202128007014

biochemical and physiological features of experimental plant material and the agar nutrient medium.

Given that the changing conditions of plant cultivation (duration of exposure, type of explants, chemical composition of the living environment), it is possible to regulate the content of special metabolism substances.

4 Conclusion

The unique properties of plants to synthesize a wide range of bioactive substances, in particular compounds of secondary origin, makes it possible to use these natural resources. In order to preserve the biodiversity of natural biocenoses and extract the necessary substances, biotechnological methods are used, espesially plant cell, tissue and organ aceptic culture.

The results of our study fully confirm the data on the secondary metabolites extraction from the plant material and nutrient medium grown under *in vitro* conditions. It is also indicates the dependence of the synthesis of bioactive compounds on the species of plants, their origin and, accordingly, the type of explants obtained from them, as well as the exposure time and cultivation conditions.

We consider promising research of plants, cell cultures and various modifications in the chemical composition of the nutrient medium as environmentally friendly sources of pharmacologically valuable bioactive metabolites.

Abstract. The methodology of calculating parameters of the primary and secondary non-metallic inclusion formation in thermite alloys is offered. The regularities of the growth time of non-metallic inclusion in the form of corundum depending on its size, mass and quantity are analysed. It is shown that in the thermite alloy obtained by self-propagating high-temperature synthesis, the average size of corundum inclusions, surrounding the heterogeneous inclusions of chromium carbide, is 15.4 μm. It is shown that during the process of aluminothermic reactions of the SHS process a significant number of small inclusions of corundum is formed. It is shown that the alumina particles are dissolved in the alloy and they are the centers of crystallization and play the role of inoculating modifier.

Introduction

Today, one of the main indicators of metal quality and, correspondingly, the quality of final products is the contamination of non-metallic inclusions, and both the number of inclusions and their nature and physicochemical composition matter [1]. It should be noted that special attention is paid to the role of fine non-metallic inclusions in the process of the microstructure forming of steel in liquid and solid states. It is shown that the influence of fine non-metallic inclusions on the formation of the primary and secondary microstructure of steel is due to their interaction in the liquid metal melt with clusters, as well as the action of both crystallization nuclei and inhibitors of growth of the primary crystals [2]. Non-metallic inclusions significantly reduce the technological and mechanical properties of steels, contributing to the formation of various defects. One of the ways to solve the important task to increase the strength and plasticity of steels is to reduce contamination by non-metallic inclusions, reduce their size, and ensure their even distribution. During the different influences, the diverse kinds of phase and structural rearrangements occur in non-metallic inclusions, which contributes to the size changes of inclusions, their phase and structural state modifications and undoubtedly affects the local areas of the steel matrix near non-metallic inclusions. The nature of these modifications can significantly change the adhesion bonds at the inclusion-matrix interfacial boundaries [3]. The problem of controlling non-metallic inclusions is based primarily on the estimation not only of the inclusion's total number, but also the inclusion's critical size, and the assessment of the compositions; the size-based distribution of inclusions [4].

One of the unsolved problems of the metallurgical processes theory is the reliable calculation of the mass, size, and composition of non-metallic inclusions in steel. There is a large array of experimental data on this topic, but the available theoretical developments can only claim to solve certain aspects of the problem for a few classes of non-metallic inclusions [5]. Thus, in [6, 7] there is a systems review of non-metallic inclusions FeO-MnO-SiO_2-Al_2O_3, which are most common in the practice of steelmaking.

In [3] the processes of steel destruction near non-metallic inclusions are analyzed and the peculiarities of the structure of inclusions as phases of introduction and their influence on the occurrence of the thermal and deformation stresses are discussed. The author shows the influence of the non-metallic inclusions nature on the mechanism of microdestruction formation in steel under the different deformation conditions; and also - inactive areas.

Based on Gibbs' method of chemical potentials, the thermodynamic relations, describing the origin and growth of non-metallic inclusions in steel, were obtained [8]. The influence of non-metallic inclusions on the properties and structure of the different types of steel is described in [9-16]. The influence of the morphology of non-metallic inclusions on the destruction of high-strength corrosion-resistant steel was carried out in [17]. The conditions for reducing the content of non-metallic inclusions, such as oxide and sulfide in corrosion-resistant nitrogen-containing steel, are considered in [18]. The authors in [19] proposed measures to reduce the size and number of non-metallic inclusions in the cord steel. They used the method of estimating non-metallic inclusions, which was developed by the author [20]. The share of the area occupied by non-metallic inclusions is one of the evaluation criteria.

The estimation of large single non-metallic inclusions in steel in accordance with the statistics of extreme values is given in [21].

The method for determining the mass of corundum inclusions in steel was proposed in [22]. In order to do this, the concentration of aluminum bound in oxides was found firstly:

$$[Al]_{oxigen} = [Al]_{general} \cdot 0{,}675. \quad (1)$$

Then, using the known molar mass of the elements in the formula of alumina, and knowing the mass of the metal in the ladle, the mass was determined:

$$m_{Al_2O_3} = \frac{[Al]_{oxigen} \cdot 1{,}89 M_{Me}}{100\%}. \quad (2)$$

Analysis of the impact of corundum inclusions on the mechanical and technological properties of steel shows the contradictory nature of research. Thus, the authors of [23] argue that the inclusion of corundum impairs the technological properties of steel, especially if they form clusters. And in [24] it was noted that corundum does not have a negative effect on technological plasticity, but on the contrary, even increases it, while cracks are usually formed in silicates.

On the example of simple carbides (M_6C, $M_{23}C_6$, M_3C, M_7C_3, M_2C and MS types) with the help of their crystal-chemical and thermodynamic analysis the influence and probability of phase transitions, in both liquid and solid steel under the thermal and thermoplastic influence, were evaluated in the work [25]. The study of the specifics of the influence of alloying elements on the composition of carbides of the MS and M23C6 types in the multicomponent Ni – 13.5Cr – 5Co – 3.4Al – 4.8Ti – 7.3W – 0.8Mo – 0.015B – 0.12C system was carried out in work [26].

In the work [27] the attention was paid to the study of the structure and properties of a wear-resistant alloy, based on cobalt with niobium carbide. The work [28] is devoted to the study of the regularities of combustion of powder and granular mixtures of Ti-C-Ni with the different mass fraction of Ni in the mixture and the analysis of synthesis products by the different methods. It is shown that the average grain size of carbide is 2-4 μm, which is an order of magnitude smaller than the original size of titanium particles (50 μm), i.e. during combustion is the so-called «self-dispersion» of titanium particles, and the nickel bond prevents the growth of titanium carbide synthesis.

The issue of predicting the release of carbidonitrides and carbides in microalloyed steel using thermodynamic calculations is disclosed in the work [29]. The calculation of the chemical composition and total mass of non-metallic inclusions in the course of out-of-furnace processing and casting of steel is given in the work [30]. The authors of the following work [30] found that the composition of inclusions in both deoxidized and non-deoxidized aluminum steel is well amenable to thermodynamic modeling taking into account the influence of slag and other factors, for example, the receipt of aluminum as an impurity in ferroalloys).

The above confirms the need to expand research in the field of studying the effect of non-metallic inclusions on the physicochemical properties and structure of steel.

The issue of calculating the parameters of formation of non-metallic inclusions is insufficiently studied, so it seems appropriate to propose a method of calculating the parameters of formation of non-metallic inclusions, as the primary as secondary in thermite alloys.

Results and discussion

It is known that in order to obtain a dense SHS-material with high physical and mechanical characteristics, it is necessary to take into account the patterns of combustion of the reaction mixture, the formation of chemical and phase compositions of the final product, the crystallization behavior of the alloy [31]. As it is noted in [32] during the formation of a thermite alloy layer of the Fe-Cr-C system on a metal-based SHS process, the layer formation zone is characterized by macrostructure stability and positive effect of oxidative nonmetallic inclusion in the form of corundum (as α-modifications of Al_2O_3). Corundum, creating the effect of inoculating modification of the thermite alloy, in turn, promotes the formation of chromium carbides in the resulting thermite alloy.

The total reaction, which determines the overall material balance of the process of forming a layer of thermite alloy in the SHS process, has the form [33]:

$$6(Fe_2O_3)_{sl}+6(Al)_{sl}+13(C)_{sl}+(Fe)_{sl}\rightarrow 9(CO)\uparrow+(C)\uparrow+$$
$$+(Fe)\uparrow+Fe_{Me}+3(Fe_3C)_{Me}+(Al_2O_3)_{Me}+2(Al_2O_3)_{sl}. \quad (3)$$

The reaction of formation of chromium carbides has the following form:

$$2(Cr)_{Me}+(C)_{Me} \rightarrow (Cr_2C)_{Me}. \quad (4)$$

In the formed layer of thermite alloy complex carbide phase contains 78.7% of the mass. Fe + 14.6% of the mass. Cr + 6.7% wt. C and/ is formed according to the reaction:

$$Fe_{Me}+3(Fe_3C)_{Me}+(Cr_2C)_{Me}\rightarrow Fe_{10}Cr_2C_2\rightarrow 2(Fe_5CrC). \quad (5)$$

The distribution of chemical elements of charge materials in the formation of a layer of thermite alloy based on iron, the SHS process is determined according to the method [33] from the material balance of the reaction (3):

$$\Sigma(3+4):\ 6(Fe_2O_3)_{sl}+6(Al)_{sl}+2(Cr)_{sl}+14(C)_{sl}\rightarrow 9(CO)\uparrow+$$
$$+(C)\uparrow+(Cr)\uparrow+(Fe)\uparrow+Fe_{Me}+3(Fe_3C)_{Me}+(Cr_2C)_{Me}+$$
$$+(Al_2O_3)_{Me}+2(Al_2O_3)_{sl}. \quad (6)$$

Due to the fact that the liquid phase of the thermite melt is stored on the metal surface of the casting for a short time (15-25 seconds), mixed in the formed functional layer corundum does not have time to affect the slag in full and affects the formation of metal structure.

According to [34], the formation of a new phase inside the melt begins with embryos. Embryos, as a new phase, can be formed when the melt is supersaturated with the components of the new phase.

If we imagine that the nuclei of the new phase are formed on the seed, we should take into account their higher solubility and higher melting point compared to the formed metal phase solid + liquid with larger crystals. Therefore, for further growth, the embryos of the new phase must exceed some critical size.

During aluminothermic reactions of the SHS process, a melt consisting of iron and aluminum oxides is formed firstly. If in the first approximation we accept the inclusion of critical size in the form of a spherical embryo, then to calculate the formation of the embryo from the melt, we can use the formula [34]:

$$r_k = \frac{2\sigma_{SL} \cdot M_r}{\rho RT \ln C_r / C}, \tag{7}$$

where r_k – critical radius of the embryo, cm; σ_{SL} – interfacial tension, erg/cm^2; $C_r/C=\alpha$ – melt supersaturation; M_r – molecular weight of non-metallic inclusion, g/mol; ρ – density of the chemical compound, kg/m^3; R – gas constant, which is equal to $8{,}3143 \cdot 10^7$ erg/mol; T – melting point of the compound, K.

The supersaturation of the melt for alumina is equal to:

$$\alpha_{Al_2O_3} = \frac{K_f}{K_{Al}} = \frac{[\%Al]_f^{\,n} \cdot [\%O]_f^{\,m}}{K_{Al}}, \tag{8}$$

where K_{Al} – equilibrium constant of aluminum; f– index indicating the actual concentrations of aluminum and oxygen dissolved in liquid iron.

According to the formula of alumina Al_2O_3, the values n = 2 and m = 3 are taken.

The maximum solubility of oxygen in liquid iron is 0.17%.

Determine the equilibrium constant for aluminum at a temperature of 1873 K according to the formula:

$$\lg K_{Al} = \frac{-64000}{1873} + 20{,}48.$$

Accordingly:

$$K_{Al} = 2{,}046 \cdot 10^{-14}.$$

$$\alpha_{Al_2O_3} = \frac{[30]_f^{\,2} \cdot [0{,}17]_f^{\,3}}{2{,}046 \cdot 10^{-14}} = 1{,}71 \cdot 10^{16}.$$

Let's accept for oxidative non-metallic inclusion in the form of Al_2O_3:

$$\sigma_{SL\ Al_2O_3} = 23373\ \ erg/cm, \ln \alpha_{Al_2O_3} = 37{,}377.$$

Substituting the obtained data, the critical radius of the embryo Al_2O_3 is equal to:

$$r_{k_{Al_2O_3}} = \frac{2 \cdot 2337 \cdot 102}{4 \cdot 8{,}3143 \cdot 10^7 \cdot 1873 \cdot 37{,}77} = 2{,}095 \cdot 10^{-8}\,cm.$$

Substituting the obtained data, the critical radius of the embryo Al_2O_3 is equal to:

Calculate the critical radius of chromium carbide inclusions (Cr_3C_2), taking the chromium content of 28% and the carbon content of iron in 4%.

Determine the equilibrium constant for chromium at a temperature of 1873 K according to the formula:

$$\lg K_{Cr} = \frac{-20260}{1873} + 7{,}357.$$

Therefore K_c=0.0316

The supersaturation of the melt for chromium carbide is equal to:

$$\alpha_{Cr_3C_2} = \frac{K_\phi}{K_{Cr}} = \frac{[\%Cr]_f^{\,n} \cdot [\%C]_f^{\,m}}{K_{Cr}}, \tag{9}$$

According to the formula of chromium carbide Cr_3C_2 values are n = 3 and m = 2.

Then we get:

$$\alpha_{Cr_3C_2} = \frac{[28]_f^{\,3} \cdot [4]_f^{\,2}}{0{,}0316} = 11114937,\ \ \ln \alpha_{Cr_3C_2} = 16{,}22.$$

To determine the interfacial tension of non-metallic inclusions should take into account their melting point. According to [34], we assume the melting temperatures of Al_2O_3 and Cr_3C_2 are equal to 2044 ^{0}C and 1895 ^{0}C, respectively. Calculate the interfacial tension for chromium carbide:

$$\sigma_{SL\ Cr_3C_2} = 3{,}328 T_m - 4416,$$

$$\sigma_{SL\ \ Cr_3C_2} = 3{,}328 \cdot 1895 - 4416 = 1890 \quad эрг/cm^2.$$

Substituting the obtained data, the critical radius of the embryo Cr_3C_2 is equal to:

$$r_{k_{Cr_3C_2}} = \frac{2 \cdot 1890 \cdot 180}{6{,}68 \cdot 8{,}3143 \cdot 10^7 \cdot 1873 \cdot 16{,}22} = 24{,}032 \cdot 10^{-8}\ \ cm.$$

The critical size of the non-metallic inclusion of Al_2O_3 is $3.85 \cdot 10^{-23}$ cm^3, and Cr_3C_2 - $2{,}746 \cdot 10^{-22}$ cm^3.

It should be noted that the probability of formation of the critical size of the embryo of non-metallic inclusion increases with decreasing its size and increasing the supersaturation of the melt [35]. Therefore, the probability of homogeneous nucleation of alumina inclusions is much higher than the inclusions of chromium carbide.

Chromium carbide inclusions are formed heterogeneously on oxidative inclusions of Al_2O_3 as on seeds. This statement is reflected in the macrostructure of the iron-based thermite alloy sample, where a significant number of carbide inclusions surround small crystalline inclusions, which were identified by the metallographic analysis as corundum inclusions (Fig. 1).

The metallographic analysis shows that the average size of corundum inclusions surrounding the heterogeneous chromium carbide inclusions is 15.4 μm ($1.54 \cdot 10^{-3}$ cm).

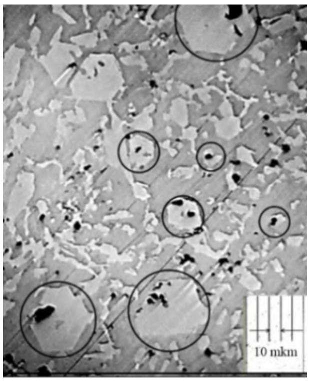

Fig. 1. Inclusion of corundum in the macrostructure of iron-based thermite alloy.

The nature of nonmetallic inclusions concentrated in a thermite alloy obtained by the SHS process on pure iron powder as a metal filler was investigated on undigested metallographic sections on an MIT-8 optical horizontal microscope (light field mode). Used iron powder by PZHRV brand 2.300.28 (GOST 9849-86) fraction <300 μm.

Analysis of the macrostructure of sample №1 showed that nonmetallic inclusions, probably of exogenous origin, are rare in the metal base (Fig. 2, a). Mostly disoriented oxides up to 5 μm in size were observed. The formed layer of thermite alloy presents globular and acute inclusions of Al_2O_3 (Fig. 2, b), which were identified as the primary inclusions that were not removed from the metal.

In sample №2 in the formed layer of the thermite alloy there are globular inclusions of pink color, which can be identified as iron oxides (Fig. 2, c). In the area close to the surface, there are elongated clusters of corundum inclusions, and exogenous slag inclusions of the products of the reaction of iron oxide with aluminum (Fig. 2, d). In sample №3 in the formed layer of thermite alloy there are accumulations of small inclusions of corundum (Fig. 2, e, f), inclusions of chromites (Fig. 2, g) (it should be assumed that chromium got into the thermite charge from rolled scale) and exogenous slag inclusions (Fig. 2, h).

To obtain a wear-resistant alloy was added to the thermite charge carburetor for carburization in the form of a modifier by MK91Abrand fraction up to 5 mm and chromium powder by PHA brand (GOST 14-00186482-051-2005) fraction 300 μm. Analyzing the macrostructure of the formed thermite alloy layer, it was determined that the carbide component predominates in the samples (Fig. 3).

In the process of alumothermic reactions of the SHS process, a significant number of small inclusions of corundum are formed, which serve as centers of crystallization in the formation of carbide inclusions and play an important role in the nucleation of chromium carbides.

It should be noted that taking into account the presence of metallic chromium in the initial charge during the formation of a layer of thermite alloy based on iron, which significantly reduces the final melt temperature, we assume it equal to 2000 ^{0}C, which is much lower than boiling temperature at atmospheric pressure of iron and aluminum.

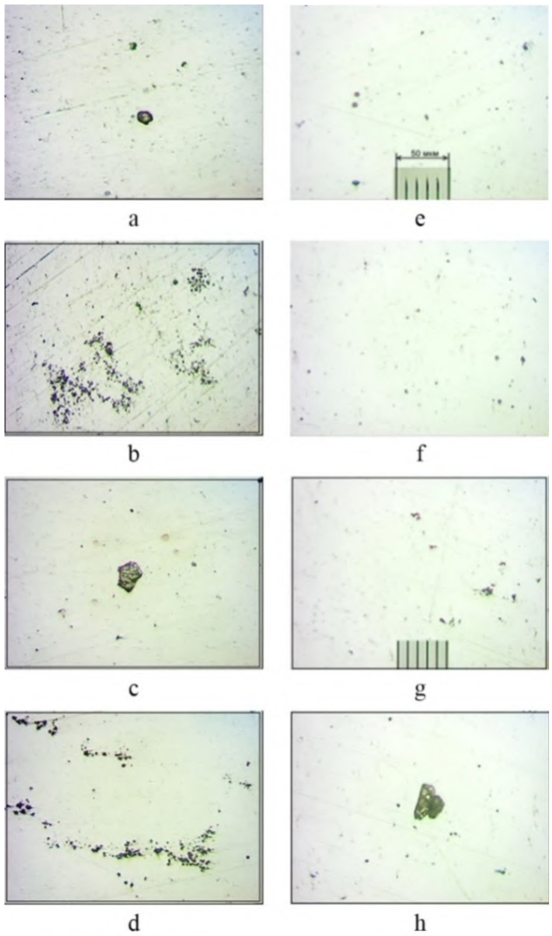

Fig. 2. Macrostructure of thermite alloy obtained by the SHS process on the pure iron powder of PZHRV brand 2.300.28.

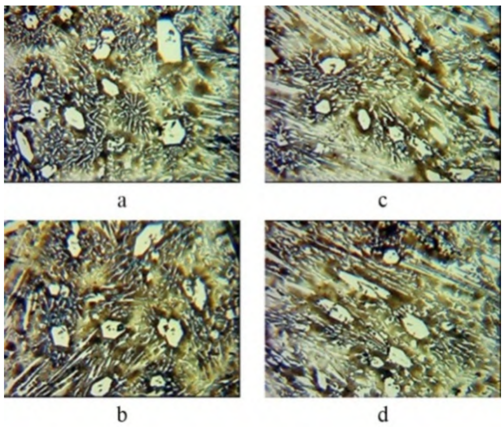

Fig. 3. Macrostructure of the thermite alloy obtained by the SHS process with the addition of PHA chromium powder: (a) –(d) - samples №1-№4 (with etching).

It is known that most of the aluminum is consumed in the process of aluminothermic reaction of the SHS process. According to the diagram of the state of the iron - aluminum part (Fig. 4), about 5% of aluminum dissolves in liquid iron at a temperature of 1536 ^{0}C.

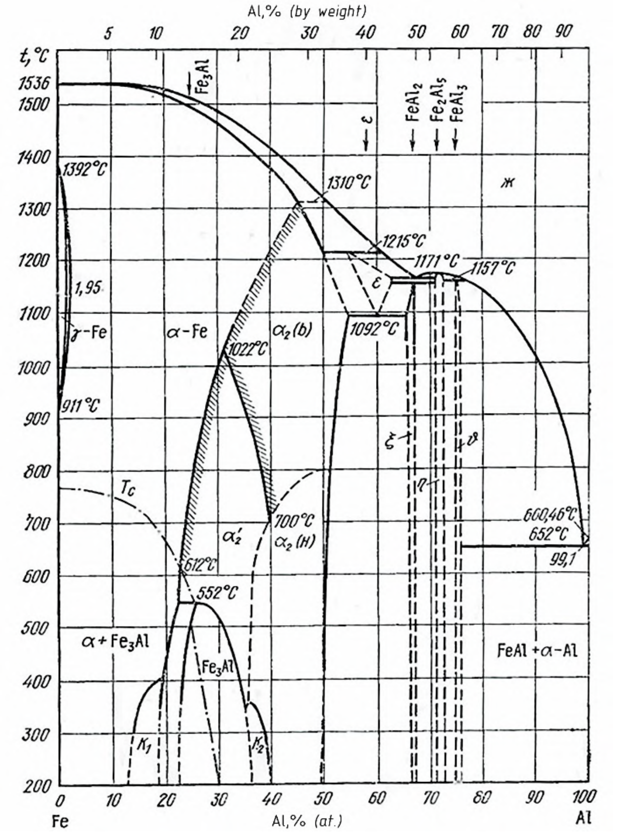

Fig. 4. State diagram of iron-aluminum [36].

Therefore, it seems appropriate to determine the supersaturation of the components that form non-metallic inclusions of corundum in the molten iron.

For the primary inclusions, the equilibrium constant according to the formula of Hoxen and Chipman [34] is:

$$\lg K_{\mathrm{Al}}^{\mathrm{pi}} = \lg(a_{Al}^2 a_O^3) = -\frac{64000}{T} + 20{,}48.$$

At the temperature of 1973 K it is equal to:

$$\lg K_{Al}^{pi} = -\frac{64000}{1973} + 20{,}48 = -11{,}96.$$

Therefore:

$$K_{Al}^{pi} = 10^{-12}.$$

According to the dependence of the solubility of oxygen in iron on temperature (Fig. 5), we assume the solubility of oxygen equal to 0.339% at a temperature of 1973 ^{0}C.

At a temperature of 1973 ^{0}C we take the solubility of oxygen equal to 0.339%.

According to formula (8), the supersaturation of the melt is equal to:

$$\alpha_{Al_2O_3}^{pi} = \frac{5^2 \cdot 0{,}339^3}{10^{-12}} = 9{,}74e^{11}.$$

According to formula (7), the critical radius of the embryo Al_2O_3 is equal to:

$$r_{\mathrm{k}\ Al_2O_3}^{\mathrm{pi}} = \frac{2 \cdot 2337 \cdot 102}{4 \cdot 8{,}3143 \cdot 10^7 \cdot 1973 \cdot \ln 9{,}74e^{11}} = 5{,}152e^{-6}\ cm.$$

When determining the number of the primary inclusions, we calculate for the mass of the formed layer of thermite alloy based on iron 100 kg.

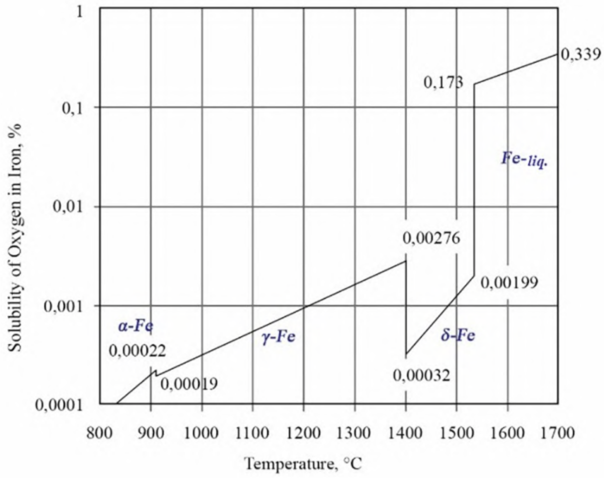

Fig. 5. Diagram of the solubility of oxygen in iron [37].

The density of the thermite alloy is 7.2 g/cm^3 and its volume is 13889 cm^3. The density of corundum inclusions is 4 g/cm^3.

The volume of non-metallic inclusion of the critical size is equal to:

$$V_{\mathrm{k}}^{\mathrm{pi}} = 4/3\pi r^3,\ V_k^{pi} = 4/3 \cdot 3{,}14 \cdot (5{,}152e^{-6})^3 = 5{,}73e^{-16}\ cm^3.$$

The mass of the non-metallic inclusion of the critical size is equal to:

$$M_k^{pi} = V_k^{pi} \cdot \rho_k,\ M_k^{pi} = 5{,}73e^{-16} \cdot 4 = 2{,}29e^{-15}\ g.$$

Both aluminum and oxygen are used to form corundum inclusions, and the limiting element is oxygen that is dissolved in the melt.

100000 g of melt contains 0.339 · 100000/100 = 359 g of oxygen (O_2).

The mass of aluminum is: 359 · 54/48 = 404 g.

The total mass of corundum is: 404 + 359 = 763 g.

Determine the number of inclusions of critical size:

$$\frac{M_{Al_2O_3}}{M_k^n} = \frac{763}{2{,}29e^{-15}} = 3{,}33e^{15}.$$

According to the work of Bogdandi L. [38], the existence of a free symmetric circular diffusion field around the embryo is assumed. Based on Fick's second diffusion law [39], the following embryo growth equation was proposed:

$$r = r_0 + 2VD(C_\infty - Cr)t, \qquad (10)$$

where r – inclusion radius to time t, cm; r_0 – the radius of inclusion at time t = 0 s, cm; V – molecular volume of oxide, m^3; D – diffusion coefficient of oxide components; C_∞ – diffusion coefficient of oxide components in the melt; C_r – concentration of oxides in the surface of the non-metallic inclusion.

For the primary inclusions, the growth of embryos is:

$$r^{pi} = 5{,}152e^{-6} + 2 \cdot 25{,}5 \cdot 1{,}5 \cdot 10^{-4}(0{,}339 - 0{,}173)t.$$

It should be noted that in the process of growth of non-metallic inclusions must follow the law of conservation of mass [40]. If two germs of non-metallic inclusions are located next to each other, then the growth of one germ of critical size is necessarily accompanied by the dissolution of the other. Therefore, as the diffusion increases, the total number of non-metallic inclusions decreases.

The change in the size of the primary inclusions of corundum depending on time is presented in table 1. It is determined that in 0.1 s the inclusions reach the dimensions sufficient for floating through the formed layer of thermite melt 10 cm thick for 6 s. Virtually all the primary inclusions are concentrated on the surface of the melt and form layer consisting of small particles of corundum.

The number of the primary non-metallic inclusions with a total mass of corundum of 763 g is calculated by the formula (Table 1):

$$N_{NMI}^{pi} = 763 / M_{NMI}, \tag{11}$$

where M_{NMI} – mass of specific non-metallic inclusions, g (Table. 1):

$$M_{NMI} = \frac{4}{3}\pi r^3 \rho_{NMI}, \tag{12}$$

Table 1. The size of the primary inclusions of corundum depending on the time of their growth.

Growth time of the primary inclusions of corundum, s	The sizes of inclusions of corundum, cm	Mass of corundum inclusions, g	Number of corundum inclusions
0,0001	0,000363	2,46e^{-15}	3,1e^{17}
0,0010	0,00147	4,44e^{-15}	1,72 e^{17}
0,0100	0,00363	9,53e^{-14}	8,01 e^{15}
0,1000	0,0115	3,87^{-11}	1,97 e^{13}

The rate of gravity sedimentation emergence of inclusions is determined by the formula:

$$V_{gs} = 2gr\ (\rho_{melt} - \rho_{NMI}) / \eta, \tag{13}$$

Where g – acceleration of free fall, which is equal to 1000 cm/s^2; r – radius of non-metallic inclusion, cm; ρ_{melt} – melt density equal to 7.2 g/cm^3; ρ_{NMI} – density of non-metallic inclusion, which for oxidative non-metallic inclusion in the form of Al_2O_3 is equal to 4 g/cm^3; η – melt viscosity equal to 0.05 MPa·s.

The rate of ascent of the primary inclusions of corundum depending on the time of their growth is presented in Table 2.

Table 2. The rate of emergence of the primary inclusions of corundum depending on the time of their growth.

Growth time the primary inclusions of corundum, p	The rate of ascent of the primary inclusions of corundum, cm/s
0,0001	0,000363
0,0010	0,00147
0,0100	0,00363
0,1000	0,0115

For secondary inclusions, the equilibrium constant according to the Hoxen and Chipman formula [31] is similar to the equilibrium constant of the primary inclusions $K_{Al}^{si} = 10^{-12}$.

The initial oxygen content of 0.173% and the final oxygen content of 0.001% are taken. According to formula (8), the supersaturation of the melt is equal to:

$$\alpha_{Al_2O_3}^{si} = \frac{1{,}5^2 \cdot 0{,}173^3}{10^{-12}} = 3{,}89e^{11}.$$

According to formula (7), the critical radius of the embryo Al_2O_3 is equal to:

$$r_{k\ Al_2O_3}^{si} = \frac{2 \cdot 2337 \cdot 102}{4 \cdot 8{,}3143 \cdot 10^7 \cdot 1973 \cdot \ln 3{,}89e^{11}} = 3{,}03e^{-8}\ cm.$$

For secondary inclusions according to formula (10), the growth of embryos is:

$$r^{si} = 3{,}03e^{-8} + 2 \cdot 25{,}5 \cdot 1{,}5 \cdot 10^{-4}(0{,}173 - 0{,}001)t.$$

We calculate the total mass of corundum, taking into account that 100000 g of melt contains 0.173· 100000/100 = 173 g of oxygen (O_2). The mass of aluminum is: 173 · 54/48 = 194 g. That is, the total mass of corundum is: 173 + 194 = 367 g

The sizes of secondary inclusions depending on time of growth are presented in Table 3.

Table 3. The size of the secondary inclusions of corundum depending on the time of their growth.

Secondary growth time inclusions corundum, s	The size of the inclusions of corundum, cm	Mass of corundum inclusions, g	Number of corundum inclusions
1e^{-8}	3,63 e^{-6}	7,8 e^{-16}	4,71 e^{17}
1e^{-7}	1,15 e^{-5}	2,53 e^{-14}	1,45 e^{16}
1e^{-6}	3,63 e^{-5}	7 e,8 e^{-13}	4,59 e^{14}
1e^{-5}	1,48 e^{-4}	2,53 e^{-11}	1,45 e^{13}
1e^{-4}	3,63 e^{-4}	7,99 e^{-10}	4,59 e^{11}
1e^{-3}	1,15 e^{-3}	2,53 e^{-8}	1,45 e^{10}
1e^{-2}	3,63 e^{-3}	7,99 e^{-7}	458915409
1e^{-1}	0,0115	2,53 e^{-5}	14512179
1e^{0}	0,036	7,99 e^{-4}	458915
1e^{2}	0,115	0,0253	14512

The number of secondary non-metallic inclusions with a total mass of corundum of 367 g is calculated by the formula (Table 3):

$$N_{NMI}^{si} = 367 / M_{NMI}. \tag{14}$$

We assume the crystallization temperature of the formed layer of thermite alloy based on iron 1500 ^{0}C, the average size of secondary oxide inclusions 1.03 e^{-3} cm, and the dynamic melt viscosity 4.26 MPa·s (Table 4).

According to formula (13) determine the rate of emergence of secondary inclusions.

Thus, in the melt with a thickness of 10 cm, the rate of ascent of secondary inclusions is 1.59e^{-3} cm/s, and the time of ascent of secondary inclusions, respectively, 6289 s. Therefore, the secondary inclusions are not removed from the thermite alloy and serve as centers for heterogeneous nucleation of chromium carbide inclusions.

Table. 4.Study of the viscosity of the steel grade ROM2SF10-MP [41].

Temperature, ^0C	Density, $\cdot 10^{-3}$ kg/m^3	Dynamic viscosity, MPa·s	Logarithm of dynamic viscosity
1400	6,60	11,70	2,460
1440	6,50	7,87	2,063
1450	6,40	7,23	1,978
1460	6,30	4,66	1,540
1500	6,12	4,26	1,451
1510	6,07	3,97	1,382
1520	6,02	2,93	1,041
1530	5,97	2,82	1,038
1550	5,88	2,77	1,020

Conclusions

The calculation method of parameters formation of the primary and secondary nonmetallic inclusions in thermite alloys is offered. The regularities of the influence of the growth time of non-metallic inclusion in the form of corundum on its size, mass and quantity are analyzed. The regularities of the formation of chromium carbides around oxidative nonmetallic inclusions in the form of corundum during the crystallization of a thermite alloy are shown. The formation of chromium carbide inclusions occurs sequentially: first the homogeneous nucleation of corundum inclusions, and then the heterogeneous formation of chromium carbide inclusions. It is determined that the volume of the critical size of the nonmetallic inclusion in the form of Al_2O_3 is $3.85 \cdot 10^{-23}$ cm^3, and in the form of Cr_3C_2 - $2{,}746 \cdot 10^{-22}$ cm^3.

It is shown that in a thermite alloy obtained by self-propagating high-temperature synthesis, the average size of corundum inclusions surrounding the heterogeneous inclusions of chromium carbide is 15.4 μm. It is shown that in the process of alumothermic reactions of the SHS process a significant number of small inclusions of corundum is formed. This indicates that the alumina particles are dissolved in the alloy and they are the centers of crystallization and play the role of inoculating modifier. It is shown that secondary inclusions are not removed from the thermite alloy and serve as centers for heterogeneous nucleation of chromium carbide inclusions.

Abstract. Ultrasonic cleaning is one of the most promising types of cleaning in terms of environmental friendliness, cost and efficiency. The condition of the cleaning body must be taken into account for optimal control of the ultrasonic cleaning process. This allows you to irradiate only those areas that really need it. The modelling of the process of ultrasonic cleaning of bodies of different configurations and the analysis of the parameters of ultrasonic responses at different stages of cleaning were performed. This allowed us to identify the parameters by which the assessment of the process should be formed. The main parameter was the change in the time of receipt of the threshold value of the signal, and the auxiliary - the change of the nonlinearity coefficient of the second order. The change in the time of receipt of the threshold value of the signal is an indicator of dirt peeling, and the change in the nonlinearity coefficient demonstrates the approach to the final result of cleaning. These parameters became clear input data for the 3-D fuzzy interval controller. The functions of affiliation were defined and the base of rules was formed. Modelling of the ultrasonic cleaning process using the established method of estimating the course of the process and the use of 3-D fuzzy interval controller showed about 35%energy savings.

1 Introduction

Effective cleaning is an important component of both production cycles and the possibility of ongoing equipment repairs. High quality in the absence of heavy manual labour and the use of aggressive chemicals makes ultrasonic cleaning one of the most promising types of cleaning. Modern technological developments and general trends in energy saving pose new challenges to increasing energy efficiency of ultrasonic cleaning. There are several approaches to overcoming these challenges. First, it is a study of the features of physical processes that provide the process of ultrasonic cleaning. The main physical phenomenon that provides ultrasonic cleaning is ultrasonic cavitation - the implosion of bubbles that occur under the action of changes in fluid pressure during sonication. This is the release of energy, which separates the dirt from the body. Cavitation in the ultrasonic bath has a zonal distribution, so the cleaning efficiency is affected not only by the parameters of the ultrasound, but also the size of the bath, the location of the emitters. Adjusting these parameters can significantly improve the quality of cleaning, as demonstrated in [1]. The distribution of cavitation is also greatly influenced by the frequency of ultrasound, and other parameters, such as fluid temperature, ultrasound intensity, oxygen content, affect the power of cavitation [2]. The large number of interrelated parameters that affect the ultrasonic cleaning process complicate the process of forming a control based on standard methods. Therefore, another approach to increase the energy efficiency of ultrasonic cleaning is to improve the methods of controlling this process. Thus, Duran Fecir proposed to use the evaluation of the process by the physical properties of the cleaning fluid, namely: conductivity and turbidity [3]. In [4], the evaluation of the process is based on the temperature of the liquid. Such approaches increase the efficiency of ultrasonic cleaning, but ignore the real state of the cleaning body, forming a control based on indirect evaluation.

More flexible is the formation of assessment based on machine learning, which was used in [5] and [6]. In these works, the condition of the treatment facility (in both cases, part of the pipe) was assessed by applying a neural network to the received ultrasound responses. The results of these experiments prove the possibility of using the analysis of ultrasonic responses to assess the degree of contamination of the body, but the algorithms used are limited by the shape of the treatment object and cannot be applied in the general case. Therefore, it is necessary to develop an evaluation methodology that will allow you to form a control based on the state of the treatment plant of any configuration.

For greater efficiency, the control of the ultrasonic cleaning process should take into account its spatial distribution and the actual state of the cleaning body. Otherwise, there will be ultrasonic treatment of already cleaned areas or insonation with insufficiently intensive ultrasound of areas that require it. For optimal redistribution of the intensity of each emitter of the ultrasonic bath, it is proposed to use a 3-D fuzzy interval controller type 2 [7], which is essentially designed for

* Corresponding author: kravchenko@knu.edu.ua

https://doi.org/10.1051/e3sconf/202128007016

spatially distributed processes with complex expert evaluation of input parameters.

Modeling the application of a new method for assessing the state of the ultrasonic process and the formation of control using a 3-D fuzzy interval controller type 2 showed an increase in energy efficiency of cleaning by 40%.

2 Problem description

Let the ultrasonic cleaning take place with the help of m ultrasonic emitters located in the given positions and given by the intensity coefficients $u(z) = (u(z_1), u(z_2), \dots, u(\,z_m))$. Input parameters are measured in *P* spatial positions Z_1, Z_2,.. Z_p. *P* and *m* are independent. With the help of spectral analysis of ultrasonic responses, it is necessary to form a method for assessing the course of the ultrasonic cleaning process, followed by the formation of a spatially distributed control action. Carry out comparative modeling of control on the basis of the developed technique concerning traditional control of process of ultrasonic cleaning limited by a time indicator.

3 Methods for assessing the state of the course of cleaning by ultrasonic responses in the tank

3.1 Evaluation of mechanical properties of the body using ultrasound nonlinearity

Ultrasonic non-destructive evaluation is widely used to quantify the mechanical and structural properties of the body. It has established itself well in many industries and continues to expand its application [8-10]. Existing studies indicate the feasibility of using to determine the degree of heterogeneity of the mechanical properties of the body coefficients of nonlinearity of the second and third orders [9, 11- 12]

$$\boldsymbol{\beta_2} = \frac{\boldsymbol{A_2}}{\boldsymbol{A_1^2}}, \quad (\mathbf{1})$$

$$\beta_3 = \frac{A_3}{A_1^3}. \quad (2)$$

But in the case of ultrasonic cleaning, the situation is complicated by a significant change not only in the properties of the body, but also in the properties of the liquid, because some of the contaminated particles will be in a suspended state after exfoliation.

In the general case, the loss of signal intensity is described by an exponential dependence

$$I(x) = I_0 e^{-2\alpha x}, \quad (3)$$

where I_0 is the intensity of the sound wave at the entrance to the material, α is the value of the attenuation coefficient, which depends on the frequency of the ultrasonic wave and the properties of the material.

In addition, the loss of intensity will depend on the ratio of the densities of the boundary media and the speed of ultrasound in them. With this in mind, the intensity loss can be written as

$$I(x) = I_0 e^{-2\alpha x} \left(\frac{\rho_2 c_2 - \rho_1 c_1}{\rho_2 c_2 + \rho_1 c_1}\right)^2, \quad (4)$$

where ρ_1, c_1, ρ_2, c_2 are body density and ultrasound rate for 1 and 2 media, respectively.

If we take into account the absorption and scattering of suspended particles of contaminants in the substance [13], we obtain the following general view for the reflected intensity, which will be returned to the sensor when the reflected ultrasonic wave from the body

$$\begin{aligned} I(x) &= I_0 e^{-\sqrt{n}(1-\eta)} e^{-2\alpha x} \left(\frac{\rho_2 c_2 - \rho_1 c_1}{\rho_2 c_2 + \rho_1 c_1}\right) e^{-\sqrt{n}(1-\eta)} = \\ &= I_0 e^{-2\alpha x} \left(\frac{\rho_2 c_2 - \rho_1 c_1}{\rho_2 c_2 + \rho_1 c_1}\right) e^{-2\sqrt{n}(1-\eta)} = \\ &= I_0 e^{-2\left(\alpha x + \sqrt{n}(1-\eta)\right)} \left(\frac{\rho_2 c_2 - \rho_1 c_1}{\rho_2 c_2 + \rho_1 c_1}\right) \end{aligned} \quad (5)$$

where $\eta = \int_0^\infty \exp\left\{-\frac{1}{V}\sigma(\lambda, r) Z\right\} \varphi(r) dr$ is concentration by size; $\varphi(r)$ is particle size distribution function, $V = \frac{\pi d^2}{4} Z$ - where *d* is the diameter of the emitter, *z* is the distance to the body, $\overline{n}$ is the average concentration of solid particles in the liquid.

According to formula (5) we obtain the largest change in the value coming to the sensor when changing the ratio at the boundary of the media, ie with complete purification. The change in intensity also significantly depends on the thickness of the contamination, the concentration of contamination in the liquid and the particle size distribution.

Also during cleaning there is a change in the configuration of the body, which also affects the parameters of the ultrasonic signal received by the sensor. To determine the influence of the features of the body configuration on the time of receipt of the threshold value and the nonlinearity coefficients of the second and third orders, modelling was performed for different shapes of the body and the corresponding values were calculated..

3.2 Modelling of ultrasonic cleaning bodies of different configurations

K-wave was chosen as the simulation software. The advantage of this product is the simulation of large-scale propagation of ultrasonic waves in a reasonable time [14-15]. The sensor and the emitter were located in the lower right corner of the simulated area. The section of the cleaning body was set with a density ρ = 7800 kg / m^3 and the speed of propagation of the ultrasonic wave c = 5100 m/s, which corresponds to the metal product. The contamination was determined by the density ρ = 3100 kg / m^3 and the speed of propagation of the ultrasonic wave

 https://doi.org/10.1051/e3sconf/202128007016

c = 2500 m / s, which corresponds to corrosion. The following were chosen as different shapes of areas: the sector of a circle, the sector of asteroids and the sectors of a circle and asteroids with holes. Ultrasonic responses were recorded for the body of each configuration and with different thickness of contamination. These responses were processed using a fast Fourier transform and obtained the values of the largest 3 amplitudes (Table 1).

For clarity, we construct graphs of dependences (Fig. 2), which show that the presence of a cleaned hole causes an increase in the nonlinear component (second-order coefficient) regardless of the geometric shape of the body.

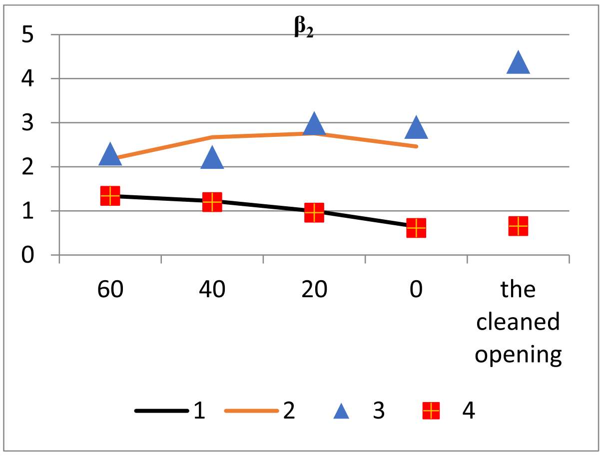

Fig. 1. Nonlinearity coefficient of second order with different thickness pollution.

For the sector range - significantly (from 2.909 to 4.387) for astroyidalnoho sector small (0.614 to 0.66). The general nature of the change is uneven - reduction coefficient β_2 occurs when a layer of pollution below a certain level, and the increase can be observed for certain geometric shape when the layer of pollution reduced, but overall remains high. In Fig. 2 shows that for any body β_2 factor value at the last stage of cleaning is reduced.

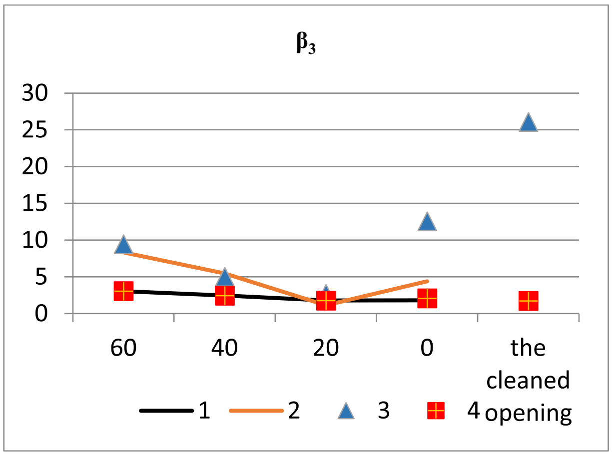

Fig. 2. Nonlinearity coefficient of third order with different thickness pollution.

Cleaning the holes, on the contrary, causes it to increase. Therefore, we can draw the following conclusion: an increase in the coefficient β_2 indicates either the cleaning of the holes, or a decrease in contamination, the layer of which remains quite significant.

The nonlinearity coefficient of the third order is even more dependent on the geometry of the body and does not show patterns in the process of ultrasonic cleaning. Therefore, the decision was limited to the analysis of only the second-order coefficient.

An important factor that has a stable behavior and allows you to assess the course of the process of ultrasonic cleaning is the time after which the threshold value of the signal. In fig. 8 shows that the change in time occurs almost linearly with a constant increase. Nonlinearity is observed only at the stage of hole cleaning, when the change in the time of receipt of the threshold signal may decrease.

With the increase of suspended particles of contamination in the liquid, the state of the liquid, not the body, has a greater influence on the response signal. There was a decrease in the time of receipt of the threshold signal and an increase in the main amplitude.

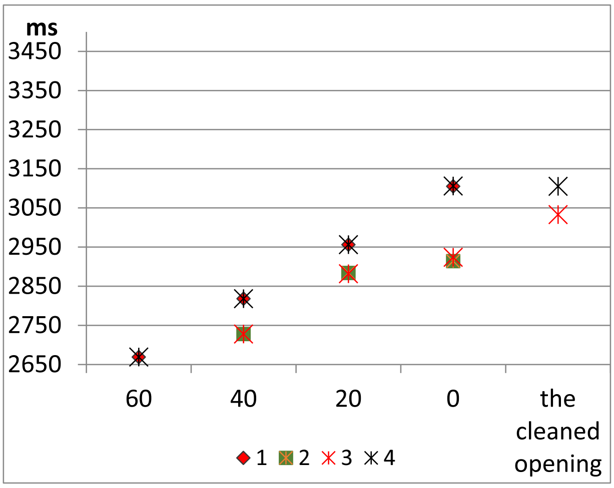

Fig. 3. The time of receipt of the threshold value of the signal depending on the thickness of the contamination for table 1 bodies.

Thus, the value of the change in the time of the signal, the coefficient of nonlinearity of the second order and the value of the change of the main amplitude, you can estimate the state of the ultrasonic cleaning, namely:

1. The change in the thickness of the contamination almost directly proportionally affects the change in the time of receipt of the ultrasonic response.

2. The coefficient of nonlinearity of the second order can determine the thickness of the contamination: a significant increase in the coefficient (more than 50%: $\frac{|4.387-2.909|}{2.909}$=0.51 for body 3 in table 2) with increasing time of receipt indicates the cleaning of various holes, ie the final stage of purification. The main amplitude decreases.

3. A less significant increase in the nonlinearity coefficient of the second order with increasing time of receipt ($\frac{|2.996-2.228|}{2.228}=0.5$ for the body 3) is evidence that the contamination is still quite significant and the area requires intensive cleaning. The behavior of the main amplitude is arbitrary.

4. The increase of the main amplitude with the decrease of the nonlinearity coefficient of the second order is a clear indicator of a stable purification process.

4 Control of ultrasonic cleaning based on 3-D interval fuzzy controller

4.1 Controller inputs

Therefore, the input parameters that will allow to assess the state of the ultrasonic cleaning process are the last two measured values of the time of receipt of the threshold signal and the nonlinearity coefficient of the second order.

The value of the "change" of the signal is obtained as the relative difference of the last two measurements of the threshold time. If this value is equal to 0, then the product of the ratios of the nonlinearity coefficients of the 2nd and 3rd orders is chosen as this parameter

$$x_1 = \frac{t_2 - t_1}{t_2}, \tag{6}$$

where t_2, t_1 are the times of receipt of the threshold value of the signal for the current and past measurements.

To determine the "purity" of the signal, we use the ratio of nonlinearity coefficients of the 2nd order

$$\mathrm{x}_2 = \frac{\beta_2^{(2)} - \beta_2^{(1)}}{\beta_2^{(2)}}, \tag{7}$$

where $\beta_2^{(2)}, \beta_2^{(1)}$ are values of the current and past nonlinearity coefficients of the 2nd order.

4.2 Membership function for inputs

The values of x_1, x_2 are normalized in the interval [-1,1]. Since the sign of the input parameter is fundamental, the normalization was not carried out evenly, but as the ratio of the found value to the maximum modulo with the same sign. For both input variables, we set five linguistic labels: significant positive (LP), mean positive (MP), zero (Z), mean negative (MN), and significant negative (LN). Given that the current value of the signal received by this sensor is most affected by the state of the immediate environment, the following type was chosen for the membership functions

$$\begin{aligned} \underline{\mu}(x_i, z) &= \exp\left(-\frac{\left((x_i-a)^2 + 2\left(\left|2\left|z-z_0\right|-1\right|-1\right)^2\right)}{\sigma_1}\right) \\ \overline{\mu}(x_i, z) &= \exp\left(-\frac{\left((x_i-a)^2 + 2\left(\left|2\left|z-z_0\right|-1\right|-1\right)^2\right)}{\sigma_2}\right) \end{aligned} \tag{8}$$

where $\underline{\mu}(x_i, z)$ та $\overline{\mu}(x_i, z)$ are the upper and lower values of the membership function, x_i is the crisp input, $z =$

https://doi.org/10.1051/e3sconf/202128007016

$(z_1, z_2, \dots, z_P)$ is the radial input coordinate (the sensor location),a is the value of the linguistic mark with which the membership function acquires the maximum value: for (LP) – a = 1, for (MP) - a = 0.5, for (Z) – a = 0, for (MN) – a = -0.5 and for (LN) – a= -1, z_0 is the value of the spacious radial output coordinate (radiator location), σ_1 та σ_2 – are parameters conditioned by physical properties of the cleaning tank and the number of sensors and outputs and belong to the interval [0,1], $i = 1,2$ is the number of variables. Fig. 4 shows a diagram for the linguistic mark (MN) and the output z_0 = 0.2 with σ_1 = 0.1 and σ_2 = 0.2.

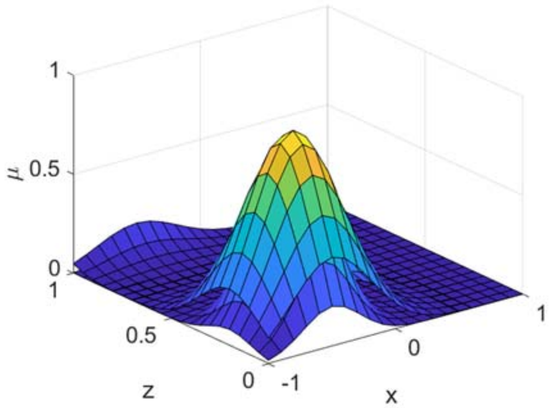

Fig. 4. Diagrams of the upper and lower membership functions for the mean positive mark (MN) for the output z_0 = 0.2;

This type of function will provide a spatial effect of the sensor signal on all emitters. At the minimum distance we get the maximum value of the function, and at the distance of the output from the input the value of the function decreases.

4.3 The rule base

Taking into account the above-described method of evaluating the course of the ultrasonic cleaning process, a base of rules for a fuzzy controller was formed (Table 2). This database is two-dimensional and does not depend on the number of sensors. Spatial distribution is taken into account through the membership functions of the input parameters. When forming the database of rules, the main role is taken into account the time of receipt of the threshold value of the signal $(\boldsymbol{x_1})$.

Table 2. The rule base

$x_2/\,x_1$	$\widetilde{LN}$	$\widetilde{MN}$	$\widetilde{Z}$	$\widetilde{MP}$	$\widetilde{LP}$
$\widetilde{LN}$	$\tilde{S}$	$\tilde{M}$	$\tilde{M}$	$\tilde{L}$	$\tilde{L}$
$\widetilde{MN}$	$\tilde{S}$	$\tilde{M}$	S	$\tilde{M}$	$\tilde{L}$
$\widetilde{Z}$	$\tilde{S}$	$\tilde{S}$	$\tilde{S}$	$\tilde{M}$	$\tilde{L}$
$\widetilde{MP}$	$\tilde{S}$	$\tilde{S}$	$\tilde{S}$	$\tilde{M}$	$\tilde{L}$
$\widetilde{LP}$	$\tilde{S}$	$\tilde{S}$	$\tilde{M}$	$\tilde{L}$	$\tilde{L}$

A negative value of this factor indicates contamination of the liquid, and a positive value indicates the peeling of the contamination.

For the second parameter, which is a relative change in the nonlinearity coefficient of the second order $(\boldsymbol{x_2})$, the following dependences: a negative value indicates that the purification is occurring and is approaching the final stage, and a positive value indicates the presence of a significant amount of contamination.

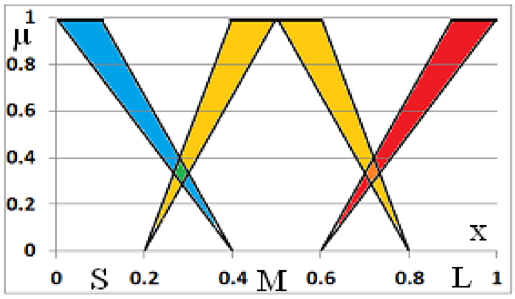

Fig. 5. Membership function for output.

The original membership function is two-dimensional and determines the value for each emitter separately. The output function is normalized in the interval [0,1], because the clear value of the output - the intensity of the emitter - is always non-negative. The second view is shown in Fig. 5.

4.4 Algorithm of the controller based on 3-D fuzzy interval set type 2

According to work [7], the operation of the controller based on the 3-D fuzzy interval set of type 2 will occur in the following steps:

1. Obtaining a clear input according to the method described in this article and its phasing.
2. Formation of the conclusion on the basis of base of rules.
3. Combining spatial information and reducing it with a maximum operation.
3. Data accumulation and type reduction through the search for a centroid by the Karnik-Mendel algorithm [16].
4. Formation of a clear conclusion.

5 Results and discussion

To confirm the effectiveness of the newly developed method for evaluating the course of the ultrasonic cleaning process, a complete modelling of the process was performed using a 3-D fuzzy interval controller. The location of the contaminated body, 4 emitters and 4 sensors were specified (Fig. 6). The figure shows working emitters in the form of concentrated circles - purification cycle 1 (colour saturation is directly proportional to the radiation intensity). Ellipses at the boundaries of the area indicate the location of the sensors. The contamination was exfoliated at a radiation intensity at the point of contamination of more than 50% compared to the maximum.

The cleaning was carried out in 4 cycles, which is how long the complete cleaning lasted with all the emitters on. At each step, a power factor was determined for each emitter, which was normalized to [0,1]. Table 3 shows the parameters obtained for each cleaning cycle, and the power determined by them. To take into account the presence of contamination in the liquid with each cycle, increase the number of suspended particles. For a better illustration, the input parameters x_1 and x_2 in the table are not normalized, and u is given the most normalized, because it is with such power factors that the processing takes place in the next cleaning cycle.

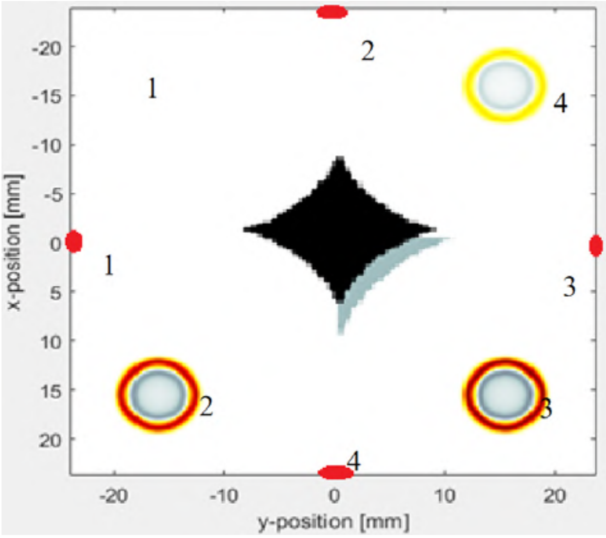

Fig. 6. Modelling of ultrasonic cleaning.

Table 3. Input and output parameters in ultrasonic cleaning.

Step #	x_1	x_2	u	Power saving, %
0	-	-	[1 1 1 1]	0
1	[0.0010 0 0.0597 0.0970]	[0.2240 0.0055 0.0015 -3.4094]	[0 0.9175 1.0000 0.3638]	42.97
2	[-0.0005 0 0.0010 0.0016]	[-0.1886 -0.3178 -0.0137 0.0778]	[0 0.4930 1.0000 0.6643]	46.07
3	[0 0 0.00051 0.00051]	[-0.0153 0.2671 0.0510 0.0100]	[0 0.7260 1.0000 0.1956]	51.96
Total			Σ[1 3.1365 4 2.2237]=10.3602	**35.25**

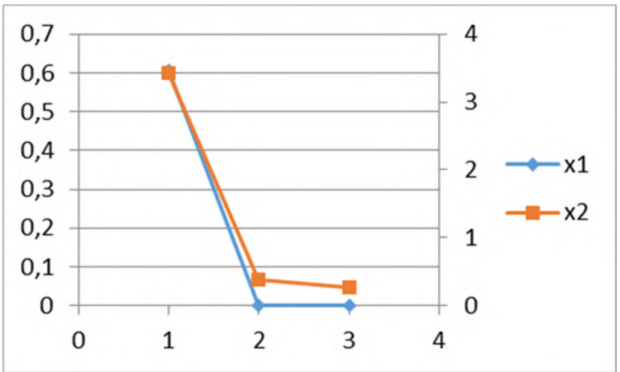

Fig. 7. Reduction of the deviation modules x_1 and x_2 by cleaning cycles.

These tables show that in each cycle, the maximum power factor of the emitter, which is closest to the contamination. At the same time, there is a constant decrease in the modulus of the vectors x1 and x2. A graphical representation of the reduction of input parameters is presented in Fig. 7.

One of the indicators of the need to stop the cleaning process is the acquisition of the limit value of the module for x_1 and x_2.

Due to the fact that the emitters did not work at full power, energy savings amounted to 35. 25% (100%-10.3602/(4·4)%).

Conclusions

In this work, a method of evaluating the course of the process of ultrasonic cleaning by ultrasonic responses was formed. To determine it, the purification of bodies of different configurations was modelled and the analysis of the received signals was performed. Parameters of responses that were considered during the analysis: the time of receipt of the threshold value of the signal and the first three harmonics. It was decided to limit the time of receipt of the signal threshold value and the nonlinearity coefficient of the second order to determine the assessment of the course of the ultrasonic cleaning process. It is the relative changes of these values and became the input parameters for the 3-D fuzzy interval controller, which performs spatially distributed control of the ultrasonic cleaning process. Energy savings using the established estimation technique and 3-D fuzzy interval controller amounted to about 35% compared to traditional control, which is limited to time only.

The authors express their sincere gratitude to Kryvyi Rih National University for support in conducting research.

Abstract. The process of thermo-mechanically controlled rolling in the conditions of Steckel mill of Ferriera Valsider plant was developed for the first time for hot-rolled coils in the sizes of 12 mm × 1510 mm from steel of X65 grade for further production of electric welded pipes according to the API-5L standard. The developed process provides carrying out of the roughing-rolling in two stages to facilitating the forming of a smaller austenite grain and therefore more dispersed and homogeneous inherited ferrite structure in the finished rolled product. At the implementation of the process, the holddown of the temperature at the desired level at 1780 Steckel rolling mill has been carried out by adjusting the number of burners in furnace coilers. The process of controlled air cooling of rolled coils to a temperature of 400 °C after winding in the developed technology for Steckel's mill condition of Ferriera Valsider plant is applied for the first time that allowed to reduce the thickness of the air scale layer and to improve the surface quality. The performed research has been allowed to evaluate the feasibility of the operating equipment and to determine the possibility of coils fabrication related to the nowadays world requirements and satisfied to the demand of European electric-welded pipes manufacturers.

1 Introduction

Ferrous metallurgy, and hot rolling in particular, is one of the most energy-consuming industries. The improvement of metallurgical technologies is referred to a modern urgently needed global trends aimed to the reducing of carbon dioxide emissions, decreasing the impact on climate change, creating the new environmentally friendly metal materials that reduce a material consumption and increase the safety of vehicles, engineering structures, pipelines and other specific infrastructure.

The most common method of making flat rolled products for large diameter pipes is rolling on plate reversible mills [1, 2], as well as on continuous rolling mills [3, 4]. A special place is occupied by the production of plate steel for pipe assortment at Steckel rolling mills. This method is less common, but is successfully used by global manufacturers. There is no analogue of the production implementation of large-diameter pipe assortment at the Steckel rolling mills in the territory of post-Soviet space. At the same time in Canada, the USA, South Korea, China, this method of production is common [5, 6].

Obtaining the required properties of the rolled steel in all cases is achieved mainly by the thermo-mechanical processing with or without of the accelerated cooling. The progressiveness of Steckel mills use lies in the significant manufacture greening through the use of heat-preserving and insulating furnace coilers, which help to reduce of the energy costs, make less the scale formation and CO_2 emissions. There are three general approaches to rolling product making that are used as inputs to the pipemaking process [7–12]: normalizing, thermomechanical controlled processing (TMCP), and quenching and tempering (Q&T). The combination of rolling processes in Steckel mills with TMCP has significant prospects at the point of view of obtaining steels of high and ultra-high strength grades, raising the standards of human safety.

The use for the manufacture of large-diameter pipes of plate or coiled steel, and hence their manufacture as longitudinal or spiral seam ones, depends largely on the political and historically formed technical and technological aspects of a particular region. While in large-scale projects in Eastern European and Asian countries are predominate longitudinal seam pipelines, in a number of European countries, as well as in Canada and the USA, spiral seam pipes are widely used [13, 14]. There are steels from X42 to X120 according to API standard using [15]. Undoubtedly, the advantages and disadvantages are available for both manufacturing options, from sheet metal products and pipes, and ending with the direct operation of pipelines.

In recent years, the process of manufacturing of hot rolled products on Steckel rolling mills has developed. The hot-rolled strength steel was the basic assortment made on such mills, producing at which is necessary to maintain temperature of metal in austenitic area. Modern Steckel mills and processes allow to produce

* Corresponding author: kvv.mariupol@gmail.com

rolled products with controlling the temperature level to obtain the desired set of mechanical properties of the finished rolled product [16–19]. Functioning mills by their design are divided into several types: single-stand, double-stand, roughing rolling stand, with additional finishing stands [16, 19].

The processes of Steckel mill rolling high-strength steels, intended mainly for the production of large pipe, were investigated in papers [20–23]. The processes proposed by the authors of works [20, 21, 24], related to the production of rolled products for large diameter pipes of steel grade X80, are of practical importance. It should be noted that these technologies are implemented on the equipment created in the 1990's, which allows to conduct a particular analysis of technical capabilities and differences of equipment built earlier. In paper [22], the authors present a study of the influence of temperature on the formation of structural components along the strip in the production of austenitic steels, the results of which can be partially applied in the development of the technology or its adjustment.

In works [25–30] the researches of separate processes which also using on design of a rolling at Steckel mill are presented. At indicated, temperature and strain rate conditions play a significant role in obtaining a high-quality steel structure, mechanical properties and other quality indices [25–30]. So in paper [31], the temperature drop in closed coilers is taken into account, and the theoretical consideration of the indentation of a roller tool into a slab allows one to evaluate deformation and power modes [29, 32–35]. The most important factor is the friction conditions, the forecast of which during hot rolling is carried out according to complex equations that have restrictions on the parameters of the chemical composition of rolled steels [36]. Also, the results of a study on laboratory modeling of Steckel mill rolling, which are presented in work [37] are of a particular interest. The above approaches are associated with a number of assumptions that reduce the accuracy of preventive technological solutions. Therefore, conducting research in an industrial environment at Steckel mill is a more accurate, albeit more expensive, method.

It should be noted that a limited number of studies leave open the question of assessing the technical capabilities of the existing equipment of Steckel rolling mills relate to developing a new assortment of high grade categories. From year to year, the level of customer requirements for pipe steel increases significantly and sometimes exceeds the level of requirements of standards that are regularly reviewed. A significant toughening of requirements also has applied to API 5L X65 steel [38–41], compared to the years of commissioning of the Steckel mill (in case of Ferriera Valsider plant). Hence, designing the production technology of rolled steel for pipes on the Steckel mills of Ferriera Valsider plant of steel grade X65 is an urgent task that will assess the technical capabilities of the existing equipment and establish the possibility of producing coils that meet nowadays world requirements and meet the needs of European manufacturers of electric-welded pipes.

Purpose of the research. The purpose of the work is to develop the production technology of the assortment of hot-rolled coils of steel grade X65 at the Steckel rolling mill of the Ferriera Valsider plant (Italy), taking into account the technical features of the existing heating and rolling equipment.

2 Materials and strategy of research

The main equipment of the Steckel rolling mill line of the Ferriera Valsider SpA plant is a methodical pusher furnace with six zones for heating slabs, manufactured by Bendotti company, which is heated by natural gas with a capacity of 120 t/h, mill 3170 for rolling slabs and strip plates for the Steckel rolling mill, which includes reverse duo stand with a rolling force of up to 25 MN, and a stand with vertical rolls, a seven-zone roller furnace for intermediate heating of the strip plate, which is heated by natural gas. The Steckel rolling mill includes a reversible quarto stand 1780 with a rolling force of up to 24 MN and a chamber furnace with natural gas-heated drum coilers located on both sides of the rolling mill 1780. Unit for laminar cooling of the strip after rolling with a length of 41 m, which allows to cool the metal at a speed of up to 40 °C/s. Winders for coiling the strip up to 20 mm thick.

The main assortment of the rolling mill is heavy plate and coiled rolled products for construction purposes, including resistant to atmospheric corrosion, rolled products for shipbuilding and production of parts for mechanical engineering. The assortment produced is determined by the existing technological regulations of the operation of all main equipment, i.e. high heating temperatures of slabs for rolling, about 1230 °C, high temperature of the furnace with intermediate heating of the rolling from 1100 °C to 1250 °C, high temperatures of furnace coilers about 1070 °C. It should be noted that at these temperatures there is a significant reserve of energy-power parameters. The actual rolling force in roughing and finishing stands is in the range of 12-14 MN, with a relative reduction per a pass from 15% to 50% according to the assortment, which makes possible further development of technology and expansion of the assortment. The scheme of the main technological line for the production of hot-rolled coils at the Ferriera Valsider plant is shown in Fig. 1.

In Fig. 2 the finishing stand of the Steckel mill 1780/quarto with furnace coilers and in Fig. 3 is the laminar cooling system are shows. The assessment of the plant capacity to master the technology of production of coils of pipe assortment was based on the analysis of the technical characteristics of the existing equipment.

As a result of the analysis and preliminary calculations of maximum allowable technological loads on the main equipment of the stands, with the help of mathematical modeling complex insufficient power of the main drive engines of the 3170 mill and 1780 Steckel rolling mill at quite high power characteristics of both stands, which does not allow to operate them at full

 https://doi.org/10.1051/e3sconf/202128007017

power. Based on the calculation, the following results were obtained, Table 1.

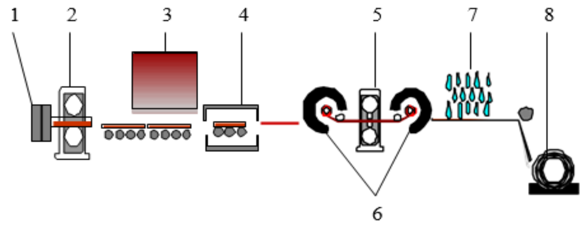

Fig. 1. The scheme of the technological line for the production of hot-rolled coils at the Ferriera Valsider plant: 1 – stand with vertical rolls; 2 – roughing stand 3170; 3 – continuous pusher furnace; 4 – continuous roller furnace; 5 – Steckel stand 1780; 6 – furnace coiler; 7 – laminar cooling; 8 – coiler.

Fig. 2. Finishing stand of the Steckel mill 1780/quarto with furnace coilers.

Fig. 3. Laminar cooling system.

Table 1. Comparison of actual and calculated engine power.

Stand/type	Number of main drive engines	Maximum rolling force, MN	Actual engine power, kW	Calculated, required engine power, kW
3170/duo	2	25	2x2240	2x4430
1780/quarto	2	24	2x4480	2x5770

Thus, improving the efficiency of the mills at the Ferriera Valsider plant by increasing productivity, reducing specific energy consumption, improving the quality of products is possible by installing new, more powerful main drive engines. Insufficient engine power makes difficulties in the development and implementation of thermo-mechanical rolling technology on the existing equipment.

Development of the production technology of the pipe assortment coils is possible in two following options. Implementation on the rolling mill of TMCP technology without accelerated cooling with the need to complete the deformation in the ferritic range, which will lead to a significant (up to 30%) loss of productivity due to the forced increase in the number of passes. In addition, when performing finishing rolling it will be quite difficult to plan and implement the operation of the furnace coilers as part of the power characteristics during coiling, and directly maintain the required temperature of rolling, which will vary widely. The use of TMCP technology with accelerated cooling is a more acceptable option. The undoubted advantage of this technology is the higher consumer properties of the products, which has been repeatedly emphasized by many studies, lower production costs, including by reducing the level of microalloying elements added to the steel, reducing energy consumption for heating and rolling. In addition, and what is especially important for this Steckel rolling mill, is the reduction of loads on the engines of the main drive and furnace coilers due to the deformation in a higher temperature range.

3 Results and Process Developing

As a billet for the production of coils with dimensions 12 mm x 1510 mm, steel grade X65 was considered the use of slabs of "AZOVSTAL IRON AND STEEL WORKS" current production, cross section 220 mm x 1510 mm. The chemical composition of the experimental slabs are given in Table 2. Slabs are heated in a six-zone methodical furnace. The heating temperature of slabs for rolling should be 1170°C ± 10 °C. Determination of the required austenitization temperature was carried out on the basis of data on the solubility temperatures of NbC and Nb particles (C, N) in the structure of a uninterruptedly-casted slab. The heated slabs enter the roughing stand of the duo mill 3170, preliminary passing the water wash box to remove furnace scale from the surface. The temperature of the slabs after the water wash should be 1130 °C ± 10 °C.

Rolling in a rough stand should be carried out according to the longitudinal scheme in two stages. The first stage of the rolling is carried out in the upper part of the austenitic area in the temperature range from 1130 °C to 1020 °C, where intensive recrystallization of the deformed austenite takes place, with a reduction of more than 10% per a pass, except for the first two or three passes, in which the reduction is limited by the maximum angle of capture, power and engine torque. After performing the first stage, the roll is cooled by translational movement on the roller conveyor to a temperature of 920 °C. The absence of deformation in this temperature range allows to keep part of the niobium in dissolved form for further dispersion hardening of the metal, as at this stage incoherent particles Nb (C, N), as well as Ti (C, N) separated, do not make significant changes in steel hardening. The last 2-4 passes are performed in the area of recrystallization inhibition in the temperature range of 920-880°C, with a reduction ≥10%.

Implementation of rough rolling in two stages promotes the formation of smaller austenitic grains, and more dispersed and homogeneous inherited ferrite structure in the finished rolled products. The thickness of the rolling should be not less than three times the final thickness. The recommended temperature-deformation modes of rolling through the passes in the stand 3170 are given in Table 3.

After rolling in a roughing stand, a 40 mm thick rolling is cooled on a roller conveyor to a temperature of 830-820 °C. Then the rolling goes to the continuous rolling furnace, where the temperature is equalized in cross section and length, as well as the side edges are heated. The temperature of the metal after equating in the rolling furnace should be 835 °C ± 5 °C.

The final rolling is carried out in the stand of the quarto Steckel rolling mill. Rolling in the Steckel stand should begin at a temperature of 825-835 °C, i.e. below the temperature of complete inhibition of austenite recrystallization, and end at a temperature of not less than 810 °C. The reduction on all passes must be at least 10%. During the implementation of the described temperature-strain parameters during finishing rolling, austenitic grains are extracted, the boundaries of which are fixed by Nb (C, N) phases released during rolling and will significantly grind the inherited ferrite grain. The recommended temperature-deformation mode of rolling on passes in a stand 1780 is given in Table 4.

9	14	12	14.29	819	11.87

The schedule of reductions is calculated so that the last pass is performed during the rolling process.

Changes in temperature and rolling force in the passes in the Steckel stand are shown in Fig. 4. In order to meet the conditions of the thermomechanical rolling process, it is necessary to maintain the temperature of the metal in the passes in the Steckel stand. When modeling the technology of maintaining the temperature at the desired level, which is low with relation to the current technology, is carried out by adjusting the number of burners in the furnace coilers.

After rolling, the strip is transferred without delay to the laminar cooling unit. The sequence of going through the technological units before laminar cooling should be as follows: (i) Furnace coiler before the mill → (ii) Steckel rolling mill → (iii) Laminar cooling. Due to the short distance of the rolling fields, the work of all technological equipment must be synchronized. Cooling of the coils on the accelerated cooling unit should be performed at a speed of 12-14 °C/s to a temperature of 560-580 °C.

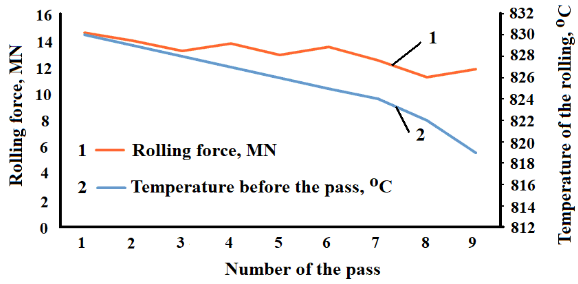

Fig. 4. Dynamics of changes in rolling force (1) and temperature (2) in the passes in the Steckel stand.

The accelerated cooling from the lower range of the austenitic area will form the final dispersed ferrito-bainite structure in the finished product. At this stage the separation of Nb (C, N) particles from the solid solution will significantly increase the strength of the metal. After the accelerated cooling, the strip is rolled into a coil on the finishing coiler. In order to reduce the thickness of the air scale, the rolled coils must be subjected to additional controlled air cooling to a temperature of 400 °C, using industrial aerators. The final slow cooling of the rolls is performed in the warehouse during 48 hours.

4 Conclusions

For the conditions of the Steckel rolling mill of the Ferriera Valsider SpA plant, the assessment of technical capacity and the development of a complex technology were conducted for the first time for the production of coils of steel grade X65 for further production of large diameter electric-welded pipes for oil and gas. The calculations were conducted and the required capacity of the main engines of rolling mills 3170 and 1780 were installed for the first time at the Ferriera Valsider SpA plant, which will increase the productivity, reduce specific energy consumption and improve the quality of produced products. In order to improve the quality of the surface of the coils, the use of controlled air cooling of the coils after coiling was proposed for the first time for Steckel rolling mill.

Abstract. The proposed method for calculating the loading parameters makes it possible to determine the wear parameters after explosion hardening. The calculation method is simple and less time consuming compared with calculation methods that involve the use of nonlinear programming methods. The main methods of increasing the wear resistance of mining equipment parts using explosion methods are generalized. The reserve for increasing the wear resistance consists in the optimization of deformation parameters during the power and thermal intensification of processes and the development of new methods and technologies of hardening. The factors (parameters) of the studied processes: explosive cladding, alloying, hardening, are formulated. Optimization of the processes under consideration is possible by decomposing the process into simpler ones with subsequent optimization of the parameters of these processes and the synthesis of the obtained solutions. For the first time, a solution to the multicriteria problem of two-stage explosion hardening is presented. It is proposed to split the process into simpler ones. Optimization criteria are proposed for each of the simplified processes. The problem is reduced to a conditional extremum problem, which is solved by composing the Lagrange function. By transforming the wear equation, the optimal ratio of strength and ductility for parts operating under abrasive wear conditions is determined.

Introduction

This research examines the processes of increasing the wear resistance of mining equipment parts using pulsed energy sources. These processes include explosive cladding with wear-resistant materials, explosion hardening, explosion-thermal hardening and frictional hardening.

The research is devoted to solving the topical scientific and technical problem of increasing the resource and operational reliability of parts and assemblies of mining equipment. This is due to the fact that at present the physical wear and tear of production assets of the mining and metallurgical complex (MMC) of Ukraine is 70-75%. The costs of repair, installation and dismantling of parts of equipment operating under intensive wear conditions are comparable with its high cost. Nevertheless, MMC occupies a major place in the national economy of Ukraine, providing a third of industrial production and more than 40% of export profits. The most effective and cheap methods for increasing the wear resistance and durability of mining equipment parts for buckets and bucket teeth for excavators, hammer crusher bits, ball and rod mill armor linings are methods of impulse hardening, alloying and cladding.

The reserve for increasing the wear resistance of mining equipment parts is optimization of parameters, power and thermal intensification of these processes, development of fundamentally new methods and technologies of hardening [1, 2]. In addition, the search for technologies for restoring the wear resistance of parts without dismantling them is also promising. Therefore, the purpose of this research consists in developing a universal analytical method for calculating the optimal parameters of the processes of increasing the wear resistance and durability of parts using pulsed energy sources.

Optimization of the problems of impulse metalworking is quite fully covered in the literature [3-8]. Most of the optimization problems of deformation and shape changing are reduced to determining the extreme values of the response parameters and the values of the corresponding determining parameters [9, 10]. The method of choosing the geometry of the deforming tool according to the criterion of the minimum surface load in the areas of contact with the workpiece is of interest [3].

In this case, the system of regularities of elastic-plastic deformation underlying the theory of rolling are replaced by variational principles. In this case, the problem is reduced to the calculus of variations and optimal control and can be studied in two ways. Either the extreme trajectories (Euler-Lagrange theory), or by experimental trajectories (Hamilton-Jacobi theory) could be determined. The task is reduced to finding «geodesic lines» which the shortest arcs connecting two are given points on a certain surface. This minimal problem is a typical example of a questions vast class for the calculus of variations.

In general, in most research, it is believed that obtaining an extreme value of a parameter is possible only for certain values of all factors, which significantly complicates the calculations and obtaining the final results. A number of researchers [11, 12] take into account the factors that are most significant, using the method of

* Corresponding author: shchetinin23@gmail.com

frozen parameters or successive approximations. To determine the significance of the factors, the values of several of them are fixed while others change. Then the values of the latter, minimizing the full power of forming, are determined [13, 14].

A number of practical problems of the metal processing theory have an alternative nature. For example, reducing material consumption increases the likelihood of stamping scrap. The solution of such problems requires the use of the mathematical apparatus of probability theory.

The design of technological processes is usually reduced to solving a multivariate problem with full or partial formalization of the compared options optimality criterion. The cost of a product could be a fully formalized, complex criterion. However, the widespread use of the cost criterion in the design of sheet-stamping production processes is difficult both due to the lack of the necessary information support for the dependence of the cost of products on the technology of its production, and on performance indicators.

It is more expedient to evaluate the efficiency of a technological process as a physical system using the state function, i.e. entropy. It is characterized by the tendency of systems to an equilibrium state, equilibrium and to equiprobable microscopic chaotic molecular processes. At the same time, plastic deformation occurs under conditions of inhomogeneity not only of the stress-strain state, but also of the structure, chemical potential, and temperature. I.e., shaping and hardening processing are characterized by a complex thermomechanical and physicochemical environment. As a result, irreversible energy flows arise, causing local entropy production.

The process of plastic deformation and the subsequent depletion of the parts resource obtained by pressure treatment methods is ultimately determined by the ratio of competing flows. This is an energy flow that seeks to destroy the metal during processing and operation, or prevents it. The predominant flow determines the reliability of the structure at this operation stage. However for problem solving, it is necessary to have a system of equations for the kinetic state of a physical object and dynamic return. At the same time, the solution and composition of these equations are considered only for some special cases without obtaining quantitative indicators.

In addition, the development of the mathematical apparatus, mathematical modeling methods and computer technology significantly increases the reliability and calculations quality. Therefore, according to a number of researches [15] experimental and static methods for studying the processes of manufacturing and operation of machines structural elements are giving way to a less costly method of mathematical modeling. Regarding the modeling of technological processes of forming parts, this really takes place [16]. The calculation technique [16] for assessing the parameters of the state of parts during manufacturing, repair and subsequent operation is the methodological basis for the development of the theory and practice of creating highly reliable structures, assemblies and parts. A set of mathematical models of the service parameters of parts evolution during operation: the accumulation of damage and a decrease in fatigue life, etc. do not solve the issues of the need for preventive maintenance and measurements of parts and structures as a whole; nevertheless, the methods of «operations research» taking into account static data allow solving a complex of problems of economics, operation and repair. However, the general strategic task of uniformity of machine parts service life is solved by the joint efforts of constructors, technologists, operators, mathematicians and economists.

However, the determination of the significance of all factors is compatible in terms of labor intensity with the procedure for enumerating all the parameters.

The foregoing allows us to state that to date, in the theory of sheet stamping production, considerable scientific knowledge has been accumulated in the use of methods of the optimal control theory and mathematical modeling to increase the efficiency of metal forming processes. The widespread use of optimal control methods for solving specific technological problems is relevant.

In conclusion of the paragraph, it should be noted that a variety of problems of the optimal control theory is inherent in the process of sheet-stamping production, and the fact that the application of the methods of this theory to shaping technologies is in it’s development stage.

Material and methods

For a functional description of the processes under consideration, it is necessary to formulate the factors (parameters) of the researched processes. The main parameters of explosion welding (kinematic and physical) include: speed of movement of the point of contact v_c, dynamic impact angle β, plate driving speed v_0, pressure, impact duration, temperature in the impact zone. In addition, the process efficiency is largely determined by the technological parameters:

– detonation velocity D, which characterizes the type of explosive charge;

– dimensionless welding parameter r – the ratio of the mass of the explosive to the mass of the driver (plate, pipe);

– distance between the welded workpieces – welding gap h.

The factors affecting the degree of explosive hardening include the applied pressure, the duration of the impact pulse, the nature of the loading, and the velocity of the linear pulse.

For explosive friction hardening the factors are the same as for explosion hardening, only instead of the linear impulse velocity the velocity of the friction material is used.

In addition, the physical and mechanical characteristics of the processed material affect the efficiency of the explosion welding process and the degree of hardening.

Optimization of the analyzed processes by theoretical analysis of numerical modeling is possible using the calculation method described in [17, 18]. The latter includes a set of models that characterize the properties of the original blanks and the evolution of these properties

https://doi.org/10.1051/e3sconf/202128007018

during processing and operation. Taking into account the fact that the researched processes depend on a smaller number of factors, we adapt the method used in structural mechanics by V.Z. Vlasov and in the processing of metals by pressure by V.I. Ershov, applying them to the processes of explosion welding and hardening by a laid-on charge of an explosive, converging shock waves, explosive-thermal, explosive-frictional, multiple combined explosion, multiple compression by reflected shock waves.

Calculation

The processes of explosion welding, hardening by converging shock waves, a laid-on charge of explosives, proceed under the action of one type of external load, the rest of the processes occur under the action of several independent or dependent loads.

In the former case the process is described by function $p_1(y_1...y_k)$:

$$F_i = F_i\begin{bmatrix} p_1(y_1, y_2, ..., y_k); \varepsilon_1, \varepsilon_2, ..., \varepsilon_l; \\ z_1, z_2, ..., z_m; S_1, S_2, ..., S_n; ... \end{bmatrix}. \quad (1)$$

In the latter case:

$$F_i = F_i\begin{bmatrix} p_1(p_1, p_2, ..., p_k),\ p_2(p_1, p_3, ..., p_n), ..., \\ p_n(p_1, p_2, ..., p_{n-1}); \varepsilon_1, \varepsilon_2, ..., \varepsilon_l; \\ z_1, z_2, ..., z_m; S_1, S_2, ..., S_n; ... \end{bmatrix}. \quad (2)$$

The processes under consideration are fast.

Therefore, practically without error, function (2) can be replaced by functions of the form:

$$F_i \approx F_i' = F_q(F_1, F_2, ..., F_n), \quad (3)$$

where F_i – parameter characterizing the efficiency of the considered process;

$p_1, p_2, …, p_k$ – factors that characterize the influence of each type of load on the process of cladding with a wear-resistant layer, hardening by the previously listed methods of explosion hardening;

$\varepsilon_1, \varepsilon_2, …, \varepsilon_l$ – factors characterizing the conditions of deformation;

$z_1, z_2, …, z_m$ – factors characterizing the properties of the deformable workpiece (geometric and physical-mechanical);

$S_1, S_2, …, S_n$ – factors describing structural transformations in the hardened material;

F'_i – the function approximating function F_i;

F_q – determines the influence of a complex of interactions of factors, p_k on F_i.

From the specific conditions of deformation hardening, functions $F_1, F_2, …, F_n$ are determined by one of the types of load.

When the process takes place under the influence of several independent external loads $n>1$ function F_q must be determined from additional conditions. To determine function F_q for the processes under consideration, the equality of the intensity of deformations is extremely uniform [17] at the minimum total power of deformation.

It should be noted that for fast processes of explosive hardening, frictional and shock-wave loading of the hardened material acts for several microseconds. Subsequent loading by a technological equipment element occurs much later and lasts several tens of milliseconds, so these processes can be considered as processes occurring under the action of two or more independent external loads.

Results

Let us consider the practical use of the analyzed method for the process of explosion-friction hardening. The steps are as follows:

1) the process is subdivided into two simple processes: explosive loading and frictional interaction of the technological friction sliding pad with the workpiece. Explosive loading by a plane shock wave of the pad-workpiece system results in the occurrence of a stressed triaxial uneven compression and driving of the technological pad. Contact friction stresses act on the contact surface of the workpiece with the tool. They have a significant effect on the final deformable state of the workpiece;

2) determining a functional link $F_i=F_i(p_k)$;

3) in accordance with equation (2), the functions F_q are determined. In this case it is considered that p_1, p_2 are not independent, but may influence each other. Here p_1 affects the speed of movement of the technological pad and the force of normal pressure between the pad and the workpiece.

4) determining the relation between factors p_1, p_2 from the condition of the minimum deformation energy when the deformations of the hardened surface are limited to the limit uniform one.

At the final stage we obtain the explosive-friction process dependence on many factors.

A method based on the decomposition of a combined process into simple ones and subsequent synthesis makes it possible to optimize the processes under consideration. Process conditions, properties of the deformable workpiece and structural changes in the surface layer of the workpiece. In this case:

$$F_i = F_i(p_1, p_2). \quad (4)$$

We expand function F_i in Taylor's series at points $(p_1, 0)$ and $(0, p_2)$ and adding the obtained results we have:

$$F_i = 0.5\begin{bmatrix} \overline{F}_1(p_1, 0) + \overline{F}_2(0, p_2) + \dfrac{\partial \overline{F}_1}{\partial p_2}\Delta p_2 + \\ \dfrac{\partial \overline{F}_2}{\partial p_1}\Delta p_1 + \dfrac{\partial^2 \overline{F}_1}{\partial p_2^2}\Delta p_2^2 + \dfrac{\partial^2 \overline{F}_2}{\partial p_1^2}\Delta p_1^2 + ... \end{bmatrix}, \quad (5)$$

where $\overline{F}_1$ and $\overline{F}_2$ are the values of the function in the said points $(p_1, 0)$ and $(0, p_2)$.

The mutual influence of factors is assessed by the sum of the terms containing the partial derivatives of the function at the corresponding points.

Since the sum of the terms containing partial derivatives is not zero ψ_Σ. Therefore, it is reasonable to determine function F_i in the form of a sum corrected taking into account function ψ_Σ and functions F_q. Unlike the methods of V.Z. Vlasov and V.I. Ershov, which are reduced to the problem of finding the extremum of several variables using numerical iterative solution methods and the method of searching for variable parameters, for example, the steepest descent, on a grid. Functions $F_1, F_2,\ldots, F_n$ are presented in the form (1), (2). At the same time, we represent elementary processes as a set of even simpler processes.

An increase in the number of factors taken into account results in a significant complication of the calculation and final formulas. An attempt to take into account only the most significant factors does not lead to a significant simplification of calculations. The approach to regarding problems of this class means that the problem of finding the optimal loading parameters is solved by numerical methods of nonlinear programming. The use of numerical methods allows finding the points of local extrema and does not guarantee the determination of the global extremum. In addition, it is not possible to perform an analysis of calculations to determine certain factors for the final result. In our case, it is the hardening deformation of the flat surface of the part, for example, the working surface of the tooth of the excavator bucket.

To maximize wear resistance under conditions of shock-abrasive wear, it is necessary to minimize the mass wear [17, 18], which after minor transformations is reduced to the form:

$$U = f\,\frac{H_a}{H_m}\cdot\frac{L\cdot b\cdot\sigma_n}{\sigma_в}\cdot\frac{(1+\delta)}{\delta}, \tag{6}$$

where U – mass wear;
f – coefficient of friction;
H_a – abrasive hardness;
H_m – hardness of the part material;
$\sigma_в$ – temporary resistance to destruction;
L, b – length and width of the contact surface;
σ_n – standard pressure;
δ – relative elongation of the part material;
β – empirical coefficient;
γ – density of the part material.

To reduce wear, it is necessary to reduce the value of the coefficient of friction, increase the hardness of the material, the temporary resistance to fracture and the relative elongation of the material of the part. The minimum value of the coefficient of friction is reached at a certain value $\sigma_n = \sigma_n^0$. Its value is largely determined by the operating conditions and the geometry of the part. The relation has no extremum by $\sigma_в$ and δ, however, if the numerator and denominator (6) are divided by σ_n, in the denominator we come to expression $\bar{\varepsilon}\cdot\delta$, where $\bar{\varepsilon} = \frac{\sigma_в}{\sigma_n}$. Since $\sigma_в > \sigma_n$, then $\bar{\varepsilon} > 1$. At the same time $\frac{H_m}{H_a} < 1$.

Product $\bar{\varepsilon}\cdot\frac{H_m}{H_a} = \lambda$ is less than 1, and the sum determined by statistical data:

$$\lambda + \delta \approx const. \tag{7}$$

In this case product $\lambda\cdot\delta$ provided (5) will be maximal when $\lambda \approx \delta$. For hardened Hadfield steel, when rubbing against granite with an interlayer of iron oxides $\lambda \approx \delta \approx 0.4$, when rubbing against manganite– $\lambda \approx \delta \approx 0.7$.

To solve the optimization problem, we proceed as follows, the axis passing from the center of the cutting edge of the charge and perpendicular to it is denoted as x_1, and the axis perpendicular to it – e. In this case, e is an arbitrary energy parameter (specific energy, impulse or pressure). As a result of calculating the deformation process (at the first stage), dependence $e(x_1)$ was obtained. It characterizes the distribution of the energy parameter along coordinate x_1. This function is approximated by an exponential, power or other dependence with its subsequent linearization by dependence $e' = A + B\bar{x}$, where $\bar{x}$ – a new logarithmic or another coordinate used for linearization. The distribution of pressure, specific impulse, energy of the placed charge over the surface of the part is described by dependence $\mu = f(q_0, D_0)$, i.e. it depends on q_0 and D_0, where q_0 – specific mass of the charge, D_0 – detonation velocity. The task is formulated as follows: find such values of parameters q_0 and D_0 at which dependence e from dependence family e' suits dependence $\mu(q_0, D_0)$ in the best way.

A quadratic functional of the following form is taken as the criterion of the optimization:

$$y_\sigma = \int_0^{x_1} \left(\mu - e'\right)^2 dx_1, \tag{8}$$

An optimization criterion for calculating shear deformations when moving a friction deforming tool is set similarly. Energy parameter dependence is presented in the form $e_F = A_F + B_F x_1$, and the located one – $\mu_F = f(q, D)$. The optimization criterion will be of the analogous form:

$$y_\tau = \int_0^{x_1} \left(\mu_F - e'_F\right)^2 dx_1, \tag{6}$$

To determine the optimal values of the parameters of the two-stage deformation process, we compose the following system of equations:

$$\frac{\partial y_\sigma}{\partial q} + \alpha_{11}\frac{\partial y_\tau}{\partial q} = 0; \tag{7}$$

$$\frac{\partial y_{\sigma}}{\partial D}+\alpha_{12}\frac{\partial y_{\tau}}{\partial D}=0\,; \tag{8}$$

$$y(q,D)=0\,. \tag{9}$$

Here α_{11}, α_{12} – Lagrange multipliers; $y(q, D)$ – the equation of coupling q and D.

Multiplying equation (7) by $\frac{\partial y}{\partial D}$, and equation (8) by $\frac{\partial y}{\partial q}$ and subtracting equation (8) from equation (7) we obtain:

$$\frac{\partial y}{\partial D}\left(\frac{\partial y_{\sigma}}{\partial q}+\alpha_{11}\frac{\partial y_{\tau}}{\partial q}\right)=\frac{\partial y}{\partial q}\left(\frac{\partial y_{\sigma}}{\partial D}+\alpha_{12}\frac{\partial y_{\tau}}{\partial D}\right) \tag{10}$$

In this case, equations (9) and (10) are solved together.

If the linear approximation of e' is rough, we use the piecewise linear approximation of function $e(x_1)$ with any required precision. After calculating the specific mass of the explosive charge at the second stage of the calculation, we determine the contribution of reflected waves and other factors.

In the future, it is planned to experimentally and numerically verify the analytical results of the calculation and implement the method in a specific technological process.

In the case of using a flat explosive charge and dependence (4) to determine the energy parameters of the external loading and the deformed state of the hardened layer of the surface of the part, an analytical solution to the problem is possible using the methods presented in [17, 19] and the expression of integral (8) in elementary functions.

The proposed method can be included as a fundamental component of an integrated mathematical model for predicting the life cycle of a certain class of parts [20-22]. These classes of part are made by the parts obtained with the methods of sheet and die forging. The complex model includes the synthesis of mathematical models of the workpiece initial state, a mathematical model of the part manufacturing process (proposed in this study), the evolution of the service properties of the part, the accumulation of damage, etc. The considered mathematical model of the part manufacturing process assumes obtaining the results of the evolution of the properties of the processed parts with their maximum approximation to the operationally necessary ones. In the material of parts obtained using the methods of plastic deformation (shaping, hardening), there are significant changes in the physical and mechanical properties and structural state. It allows to significantly affect the resource and operational reliability of the parts obtained by using combined and multi-stage deformation processes. In addition, the question of the need to use hardening processing of parts manufactured by pressure processing is being resolved.

Conclusions

The proposed method for calculating the loading parameters of combined and multi-stage deformation processes makes it possible to simplify the calculation of the parameters of the hardening process and reduce the calculation time by methods involving the use of nonlinear programming methods.

The transformation of the wear dependence by mass enabled the determination of rational parameters of the plasticity of the part depending on the ratio of the hardness of the abrasive and the surface of the part and the ratio of the normal pressure of the abrasive and the strength of the material of the part. In conclusion, it should be noted that the considered technologies can be successfully used to strengthen the elements of railway tracks, tracked vehicles, in loading and unloading equipment.

Abstract. The development of a method for drawing cylindrical parts without pressing the workpiece flange, which allows reducing the cost of production due to the use of dies without a fit ring and single-acting presses. The performed research revealed that this method results in obtaining cylindrical parts with drawing ratios typical for pressing drawing. In this case, the different thickness of the finished product is several times less compared with the same type of semi-finished products obtained by drawing with a fit ring. Steel, aluminum and copper workpieces were researched. The best results were shown by more plastic materials. This method is not applicable for materials with the less than 0.25 mm thickness.

Introduction

The method of manufacturing cylindrical parts by drawing in the cold state is used at almost all mechanical engineering enterprises, which include forging and workpiece-preparation workshops and sections. In large-scale production, rather productive drawing methods are mainly used, such as drawing with pressing the flange, with pulling ribs and sills, drawing on sheet stamping machines, drawing out from a tape, drawing out with thinning the wall, etc. [1-3]. In the medium and small batch production, the above methods are used. Other methods include stamping with elastic media, liquid and gas, soft metals, explosion stamping, package drawing, pulsating drawing, stamping with a profile tool, drawing with heating and local cooling, drawing on sheet punching hammers and hydraulic presses, drawing on hydraulic presses, rotary drawing, stamping with workpiece end support, non-pressing drawing [4-6]. In single and small-scale production, the use of most of the above methods is impractical due to the high costs and the duration of the die tooling manufacture, the use of multi-operation, which makes it difficult or almost impossible to switch to the production and development of products new types. The decisive role here will be played by partially universal or universal equipment, which can be used at any stage of manufacturing a new product [7-9].

From this point of view, the application of the non-pressing method in single and small-scale production is promising and low cost, since there is no need to complicate the equipment by the fit ring and use double- and triple-action presses. Therefore, the purpose of the work consists in the experimental research of the possibilities of the drawing method with alternating strain of the flange and the development of recommendations for production.

Material and methods

Drawing without a fold holder for flangeless parts is only possible with a low drawing coefficient $m = d/D \geq 0.75 \div 0.85$ [10, 11]. To implement this process, simple equipment is used, where the stamped part is mainly pulled to dip. It is difficult to turn a flat part into a hollow one. The process is accompanied by the formation of an insignificant amount of folds and their smoothing when pulling the cup through the gap between the die and the punch. Moreover, parts made of plastic metals and alloys with a large flange can be drawn without noticeable signs of corrugation without pressing only to a shallow depth of $h \approx (3 \div 6)\,s$. High values of h correspond to workpieces with big thickness. Drawing without pressing parts with big flange is only possible before the start of decreasing the size of the initial workpiece [5, 13, 14].

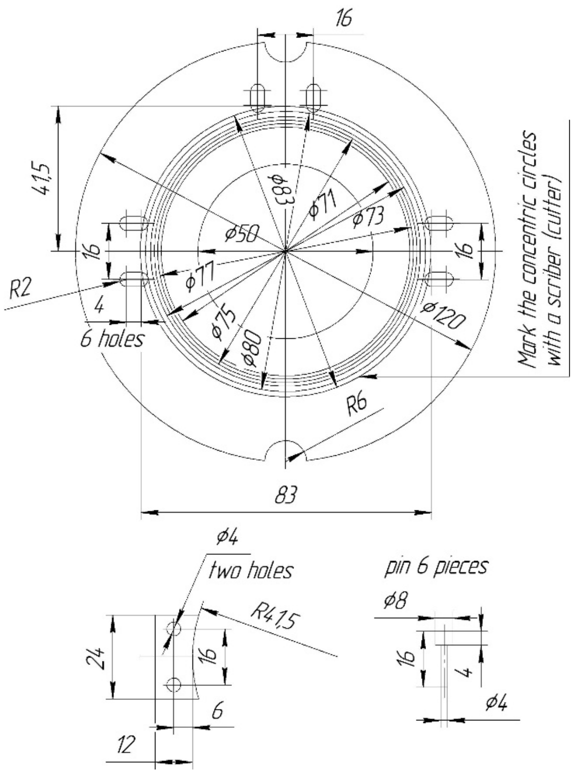
To test the possibility of obtaining high-quality cylindrical parts by drawing without pressing the flange, experimental research was carried out on round workpieces of various diameters and thicknesses. The workpieces dimensions exceeded the ultimate ones, but they were corrected according to the L.I. Shofman condition of the stability loss [11, 17]. Workpieces made of 08 kp steel, aluminum A2 and copper M4 were subjected to drawing without pressing. The diameters of workpieces made of 08 kp steel were 77, 80, 83 mm, thickness – 1.2 mm, punch diameter – 46.8 mm. For aluminum the diameters of the workpieces were 83, 86, 89 mm, thickness – 1.4 mm, the punch diameter – 46.4 mm. For copper – 58, 61, 64 mm, workpiece

* Corresponding author: argat.rg@gmail.com

thickness – 0.25 mm, the punch diameter – 49 mm. For all sizes of workpieces, the diameter of the inlet of the die was 50 mm. The radius of curvature of the die for all experiments was chosen the same and equal to 5 mm, the radius of curvature of the punch for all experiments was 4 mm.

The process of drawing without a fold holder is accompanied by the difficulty of centering the workpiece on the die and, as a result, unilateral tightening of the semi-finished product, the appearance of premature folds and destruction at the location of strains, and these processes are aggravated when using the same die for workpieces of different diameters.

a)



b)

Fig. 1. A die with centering elements: a – a photo of the die; b – a detailed outline of the matrix.

Therefore, to conduct these experiments, a universal die with movable centering elements was designed, with the help of which the workpiece was accurately aligned with the hole of the die and punch. Here, the clamps move along the radial grooves simultaneously and synchronously with each other to the center or from the center of the die, which ensures self-centering of the workpieces (Fig. 1). The ultimate diameters for drawing is performed without fold formation are: for steel – D = 76 mm, for copper – D = 56 mm, for aluminum – D = 80 mm [15-17].

Calculation

At the first stage of drawing the punch stroke was limited according to the leap in effort at the stroke-effort diagram of the tensile machine. So the corrugations formed on the flange prevent the workpiece from being pulled into the die hole. It was noted that for different thicknesses of the workpieces, the value of the stroke of the punch, at which the leap in effort was observed, was also unequal. An empirical dependence was proposed for calculating the length of the penetration of the punch into the workpiece. It accurately described this process component

$$l = r_d + r_p + s/2, \quad (1)$$

where s – the workpiece thickness; r_d – the radius of the die rounding; r_p – the radius of the punch rounding.

After the first stage of drawing passed, the semi-finished product with corrugations was removed from the die, turned by 180° and reinstalled. It was centered with the use of moving elements. The stroke of the punch was turned on and the semi-finished product was deformed until the corrugations on the flange were smoothed out. Then the punch was stopped and it was given a precisely calculated stroke until a new formation of folds of the inverse curvature on the flange. The length of the reverse stroke of the punch was calculated by mathematical dependence

$$l_2 = l_1 + \Delta h, \quad (2)$$

where l_1 – the length of the punch stroke at the first step; Δh – the addition to the reverse stroke calculated by the G. Backhaus model taking into account the Bauschinger effect [14, 18-20, 22-25].

Then the semi-finished product was removed from the die, turned over by 180º and the process was repeated until the desired product height was obtained. Thus, all batches of workpieces were drawn, and their final height exceeded the standard height of the products obtained by drawing without pressing the flange and corresponded to the height of the drawn parts with the use of pressing. So, e.g. the drawing coefficient for the aluminum part with the workpiece diameter D = 80 mm was m = d/D = 0.58, the workpiece height – h = 24.5 mm (according to the tables of Romanovskyi V.P. [17, 21, 26-28]). It is recommended to perform this drawing with pressing, cutting allowance – about *3.5* mm according to the data of Skvortsov G.D. [17, 29, 31]. I.e. the final height of the finished part is 21 mm. It is impossible to obtain such a part by drawing without pressing the flange.

Results

However, the experiment result revealed that the use of drawing with step-by-step stretching of the workpiece flange makes it possible to produce parts of sufficient quality with this ratio of the dimensions. Figs 2, 3 demonstrate drawing steps with the workpiece turning and Fig. 4 – the semi-finished products and the finished part.

Fig. 3. Drawing with turning the workpiece (material –A2 aluminum; the workpiece diameter – D = 86 mm): a – the direct stroke of the punch (the 4-th turning of the workpiece); b – the reverse stroke of the punch (the 5-th turning of the workpiece).

When conducting experiments on drawing workpieces without pressing the flange, the thicknesses of the obtained parts were also measured [30, 34, 35]. To do this, we used a micrometer thickness gauge with a measuring range of 0–25 mm and a division value of 0.01 mm to determine the strain mechanism and to formulate recommendations on the application of this process to production. The question of the legitimacy of determining the additional stroke of the punch by theoretical dependences based on the Bauschinger effect [32, 33] and recommended for use in this drawing method also remained open. Some results of the performed experimental research are presented in Table 1, which shows the dimensions of the workpieces and the drawn parts, their thickness in the characteristic zones of the profile, the material, the number of turnings to obtain the given height, the variants of the loss of stability and destruction, as well as the size of the first stroke of the punch and the addition at the reverse of the stroke load.

c)

Fig. 4. Semi-finished products and the completed part obtained by the method of step-by-step stretching of the flange (material – A2 aluminum, the workpiece diameter – 86 mm, m = d/D = 0.58, the thickness – 1.4 mm, the punch diameter – 46.4 mm, the height of the part after cutting the flange – 22 mm, the number of turnings – 8): a – the semi-finished product after the first step; b – the semi-finished product after the fourth load reverse; c – the completed part after cutting the flange.

However, it was noted that this process does not go smoothly and there are difficulties and shortcomings in the size of the stroke of the punch, as well as alignment of the workpiece after turning, which results in its destruction in the form of the separation of the bottom (Fig. 5).

Fig. 5. Pulling down of the workpiece part and it's destruction in the form of the separation of the bottom.

These phenomena's leaded to an increase in the number of rejected parts and the instability of the drawing process, which is unacceptable in the current production. Therefore, during the course of this experiment, some improvements in the die design were made and the methodology for calculating the additional stroke of the punch was improved taking into account the results of the experimental research.

Discussion

The table demonstrates that it is possible to obtain the aluminum and steel parts after at least six turnings. The number of turnings depends on the workpiece diameter and the drawing coefficient. With the larger diameter and the smaller the drawing coefficient, the greater number of the turnings is necessary to obtain a normal part. Aluminum is a more ductile metal in this case; in comparison with steel it requires a smaller number of steps with the same initial parameters and drawing coefficient. However, the thickness of the workpiece is higher for aluminum than for steel, which may explain the better stability of the workpiece flange and the possibility to obtain increased strains during one step. Drawing of thin metals by this method is difficult, because when the workpiece approaches the shape of the finished part, the corrugations are not completely smoothed out and remain on the product, which is unacceptable. Besides, the turning of thin workpieces and their strain results in a loss of bottom stability in the form of local buckling of metal. It is shown in the table for copper workpieces whose thickness is 0.25 mm.

The results of the measurements of the thicknesses of the characteristic zones of the semi-finished product allow us to conclude that the nature of the strain of the workpiece by this method is radically different from the method of the strain by drawing with a fit ring. The data in column 6 shows that the workpiece deforms along its entire perimeter. This is not characteristic of the classical drawing method, where the bottom of the part is practically not deformed, and mainly the workpiece flange is subjected to plastic strains [36, 39]. When turning, during shaping, the zone of transition of the wall to the bottom of the part and the workpiece flange are subjected to the greatest strains. Moreover, the main difference is the thinning of the flange, and not it's thickening as in the classic drawing. Plastic strain covers all zones of the workpiece and the end face of the workpiece receives compressive deformations in thickness, which indicates the large tensile stresses acting here, comparable with their value at the transition of the wall to the bottom. Based on the experimental data, the ratio of thicknesses in these zones is practically of the same order: steel – 0.83/0.81; 0.79/0.79; 0.77/0.76; aluminum – 0.79/0.77; 0.77/0.76; 0.76/0.75.

However, the experimental result revealed that the use of drawing with step-by-step stretching of the workpiece.

Conclusions

Thus, the conducted experiments confirmed the possibility of manufacturing cylindrical parts by drawing without pressing the workpiece flange with its step-by-step stretching. It will allow applying the method to a single and small batch production using simple presses and mold tools without a fold holder. However, one question remains open. It is the problem of the maximum diameter of the workpiece for this method, more precisely, the ratio of the diameter of the workpiece to the diameter of the part. Also the possibilities of stamping workpieces that are outside the range of sizes given in this research have not been analyzed.

Abstract. Erdenet copper-molybdenum deposit is the biggest one in the world and has a significant impact on Mongolian society and economy. Today LIEBHERR-994B hydraulic shovels from Germany, electric shovels including EKG-10 and EKG-15 from Russia operate for the mining works, and dump truck BelAZ - 75130 used for transportation. The causes of shovel downtime are classified as technical, technological, and organizational. During the study period, 41% of the total downtime of the excavator's park was technical, 45% was technological, and 11% was organizational downtime. For shovels, 7% of technological downtime is due to blasting, and for dump trucks 8.7%. In open-pit mining, blasting is performed on a weekly basis, so the duration of this technological downtime can be considered almost constant. If the time between blasts or period of blasting can be arranged optimally, it will be possible to reduce mining equipment's downtime due to blasting.

1 Introduction

The mining industry in Mongolia is one of the leading sectors that determine the country's economic development. The continues and efficient operation of any mining enterprise is inextricably defined with the operating costs of mining equipment, including a shovels, a dump trucks and a drilling rigs.

Operating costs are mainly dependent on the reliability of the equipment and its exploitation management. Following the growth of the world's population and the demand for mineral products, Mongolia's mining and processing sector are rapidly developing on a large scale, captivating large amounts of foreign and domestic investment. Hence, the mining sector income for approximately 30 percent of Mongolia's budget and plays the main role in the economy in terms of employment and production [1].

Due to the high capital expenditures and operation expenditure of any mining industry, continuous operation and economic efficiency depend on the proper organization of each mining process and the equipment exploitation management. Especially, it is essential to enhance profitability by increasing the utilization rate of dump trucks and shovels, which account for more than 70 percent of the total operating costs of the mining industry and reducing costs [1].

Under certain operating conditions, the profitability of a mining machinery depends on its reliability, technology, and maintenance. These parameters and factors interact with the end result of the machine's operation. In other words, maintenance costs depend on the level of reliability, on the other hand, reliability depends on the level of operation.

Therefore, in order to improve the service life of the mining machine, comprehensive research has been carried out to determine the level of reliability and technological quality during its operation, the quality of the maintenance system, and the economic viability [2].

As noted above, as Mongolia's investment and foreign relations in the mining sector expand, the use of mining machinery manufactured in Germany, the United States, the Republic of Korea, and Japan is increasing. Today, not only mining machinery manufactured in these countries but also machinery manufactured in Russia have a high level of reliability of electrical and mechanical systems based on the previous base, ergonomic problems are fully solved, equipped with diagnostic equipment, work performance information system, mechanisms, and assembly units. The operations are fully automated and manufactured at the smart machine with a high level of mechatronics [3, 4, 5].

Research and study have been performed to improve the operation and reliability level and the optimization of the process of the industry's open-pit shovelss and dump trucks, but it must be kept up to date with current technological advances.

"Erdenet Industry" state-owned corporation is one of the largest mining and processing plant in Mongolia. Nowadays, the depths of the Erdenet open-pit mine have been changed from 1,500m to 1,265m, and the experience of similar mines around the world shows that when the

* Corresponding author: khavalbolot@must.edu.mn

average transportation distance of mining rock and ore is more than 10 km and the depth of the mine is more than 100m, operating costs increase and production efficiency decreases. Due to the increasing depth and transportation distance of mining rock mass of the Erdenet open-pit mine and the declining ore grade of the deposit, the cost of mining and concentrate processing is increasing every year.

The following equipment is used for the mechanization of Erdenet open pit mining and the approach is expected to use this type of equipment until 2036 years:

- Shovels:
  - EKG15 from Russia
  - Liebherr-994B from Germany
- Dump trucks:
  - BelAZ 75130
- Drilling rigs:
  - SBSh-250MNA.

As a result of the analysis of the exploitation level of shovelss using at the Erdenet open-pit mine, the numerical values of the main parameters of their reliable operation were determined and the average level for the park is shown in Table 1.

Table 1. Shovels park reliability indicators.

Reliability indicators	Average value
Mean time between failure, hours	432
Availability ratio	0,768
Technical utilization rate	0,642
Failure flow parameters, 1/hours	0,002315
Average recovery time, hours	43,4
Specific duration of unplanned repair, hours/hours	0,0993

In order to assess the general level of the electrical shovel and dump truck utilization, the volume of the excavated and transported rock mass is shown for each type of shovels using at the Erdenet open-pit mine (Figure 1).

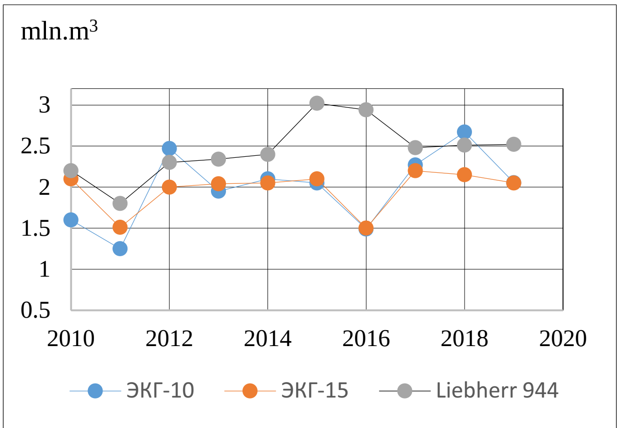

Fig. 1. Shovels' productivity by per year.

The increase in the shovels' productivity may be due to enhanced concentrator capacity. But, makes it impossible to conclude that equipment utilization has increased or downtime has decreased.

The average calendar time utilization factor for shovelss used in open pit mining is 0.75. The study defined that in the case of an shovels park, planned downtime accounts for the majority of total downtime, but it is necessary to analyze the causes of unplanned downtime to determine for opportunities to improve utilization and further study mining equipment reliability.

In general, the operation and productivity of shovels, which are the main machines in the mining industry, on the one hand, depends on the weather condition, technical state, and technological activities, the other hand, it directly affects the operation and downtime of other technological machines, such as dump trucks.

Therefore, based on the dispatcher's data, the causes for the downtime of the shovels are shown in Figure 2. It is clear from Figure 2 that 41% of the total downtime of the shovels park during the study period was technical, 45% was technological, 11% was organizational downtime and 3% was other causes [1].

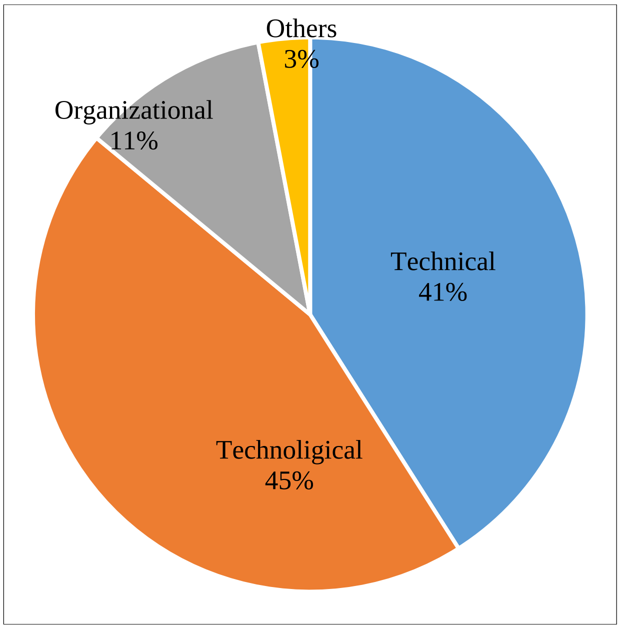

Fig. 2. The causes and types of shovel park downtime.

The causes of downtime related to the technical and technological operation and organization of shovels are classified as follows.

- The causes of downtime related to the technical:
  - Repair
  - Maintenance of one year
  - Planned maintenance
  - Unplanned maintenance due to mechanical failure
  - Unplanned maintenance due to electrical failure
  - Technical service due to mechanical part
  - Technical service due to electrical part
  - Others
- The causes of downtime related to the technological operation:

https://doi.org/10.1051/e3sconf/202128008001

- The processing plant cannot accept ore
- without operator
- without dump trucks
- The causes related to the organization:
  - due to change shovels working position
  - due to blasting
  - due to averaging and blending ore

During the study period, 55% of the total downtime due to the organization of the shovel was caused by the processing plant and 44% was due to without dump trucks (Figure 3).

Due to the close relationship between concentrator operations and open-pit mining, as of 2005, 36% of technology-related downtime was due to blasting operations, 39% due to averaging and blending ore, and 25% due to change the working position of shovels. As of 2020, 7% of technology downtime is due to blasting, 89% to averaging and blending ore, and 4% due to change shovel's working position (Figure 4).

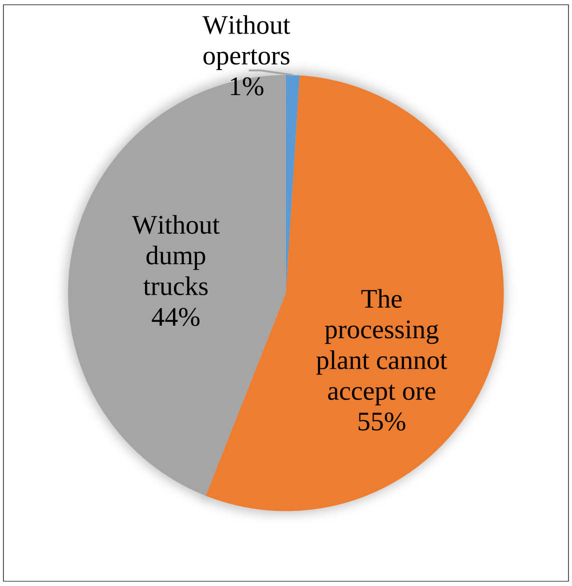

Fig. 3. The causes and types of total downtime due to the organization of the shovel.

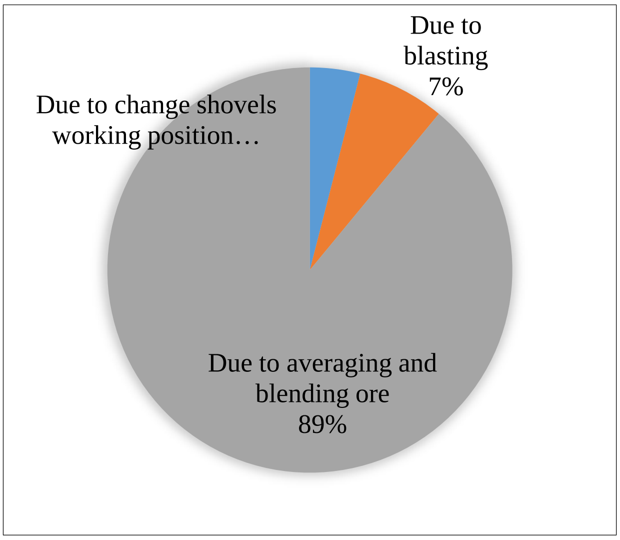

Fig. 4. The causes and types of technological downtime of the shovel.

These technological downtimes can be considered almost constant, as blasting is carried out on a weekly in the Erdenet open-pit mine, and changing the shovels working position are performed based on mining plaining and progresses. As blasting is a high-risk process, all machinery and equipment are immediately shut down to blast at the mine. The duration of blast-induced downtime is usually 1 ... 2 hours, but is very high in terms of cumulative downtime value for all mining equipment throughout the year.

Blasting is one of the most important operations in mining extraction, the purpose of drilling and blasting is to break and prepare the fragmented rocks for digging and transportation process. In the mining industry, the volume of the rock mass to be blasted per year is determined by the productivity of mining, which is one of the main parameters for selecting drilling rigs according to the rock hardness of the deposit and the bucket of shovels [6, 7, 8]. In addition to determining the number of blasts to be carried out per year and the cost of preparing 1m^3 of the rock mass for excavation and transportation work, one of the downtime's causes of mining equipment is blasting operation.

The blasting at the Erdenet surface mine is carried out every Friday at 3 pm, with a signal at 2pm to ensure the safety of workers at the open-pit and to stop all mining operations for approximately 1.2 to 1.9 hours. According to a study of the mining equipment included shovels and dump trucks, the average duration of downtime due to blasting is on average 13-28.9% just for the shovels's park. Therefore, let's consider the level of downtime due to blasting operations for the mining equipment [6].

2 Research methods

When the number of shovels in the shovels's park is 8 working at the Erdenet mine, the duration of downtime varies depending on the blasting operation, with a maximum of 865 hours and a minimum of 664 hours per year, and just for a shovel with a maximum of 93.1hours and a minimum of 83hours (Table 1).

It is also clear from Table 1 that this phenomenon is observed in the dump truck's park [6].

Table 1. The duration of downtime for the shovels and the dump trucks, due to the blasting work.

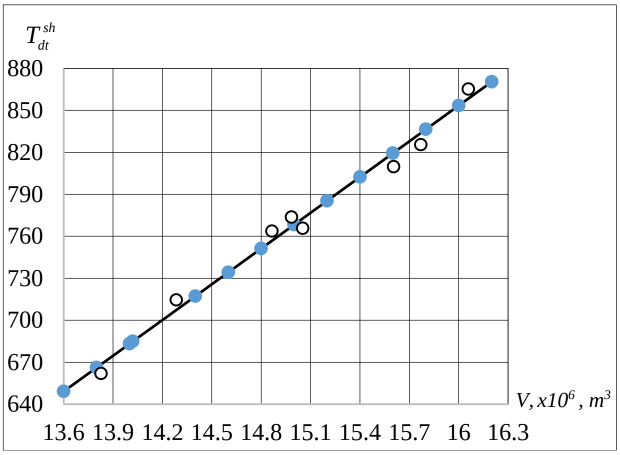
The blasted rock mass, 10^6 m^3	The average duration of downtime for the			
	the sho-vels's park	a sho-vel	the dump truck's park	for a dump truck
13.85	664	83	1560	48.1
14.36	722	92.5	1650	66
14.91	765	95.6	1860	86.5
14.988	770	96.2	1905.7	19.8
15.003	765	109.2	2100	87.8
15.556	811	101.3	2422.8	101.3
15.7	825	91.66	2350	97.9
16.105	865	96.1	2613	115.5

The blasting work is carried out once a week on the Erdenet surface mine, so approximately 52 times per year.

The duration of downtime due to blasting operation depends on the volume of the rock to be blasted per year on the one hand, and the number of blasts per year on the other, i.e. the time between two consecutive blasting works.

The volume of the blasted rock will change with the increase and decrease of the annual open-pit work. Based on the study, the duration of downtime of the shovels and the dump trucks at the Erdenet surface mine due to the blasting will be considered depending on the volume of the rock mass that will blast per year for their park.

A regression correlation (Figure 4) between the duration of downtime for shovel's park and dump truck's park during the year and the volume of the blasted rock in a given year was established and analyzed using statistical software.



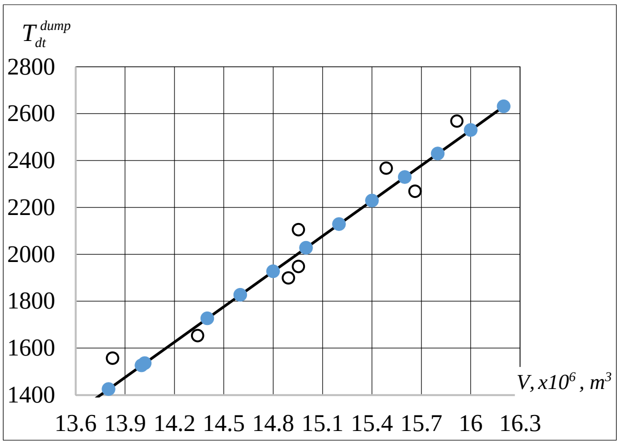


Fig. 4. Correlation between mine equipment downtime and blasting rock mass: for shovels's park; b. for dump truck's park

As a result, the relationship between the volume of the rock mass to be blasted per year and the downtime due to blasting operations:
for shovel's park:

$$T_{dt}^{sh} = -508.481 + 85.122V, \quad r = 0.923 \tag{1}$$

for dump truck's park:

$$T_{dt}^{dump} = -5503.82 + 502.1256V, \quad r = 0.817 \tag{2}$$

There is a strong correlation between the parameters under consideration since the values of the correlation coefficients r=0.923 and r=0.817 for equations (1) and (2), which show the relationship between the duration of downtime of equipment park and the volume of blasting rock mass. For equations (1) and (2), when the probability is 95%, the values of the Fisher test are F (1.6) = 42, F (1.6) = 37, and the total error are 5.62, 7.8, indicating that the relationship is correct.

The number of blasting blocks will be determined by the volume of the rock mass to be excavated during the year. By reducing the number of blasting per year and optimizing them, it is possible to decrease the downtime of shovels, dump trucks, and other machinery used at the mine. As result, this will allow them to improve their work to a certain extent.

Therefore, it is necessary to define the optimal number of blasting per year. The mining machine's production is limited by the shovel's production, which is the head mining equipment. Hence, it is essential to determine the number of blasting per year and the volume of rock to be blasted once concerning the shovel's operation.

The purpose of preparing the rock for excavation is to ensure the continuous operation of the shovel. Therefore, based on the theory of supply or resource allocation, let's determine the volume of a one-time blasting by dynamic programming.

The purpose of resource allocation theory is to determine the optimal amount of product supply (S), average resource level (Sd), inter-supply time, or supply rotation interval (t) depending on the level of consumer demand and supply. In resource management theory, the following conditions are considered in several variants [9]. These include:

- ✓ reserve intervals are different, and the amount of supply is constant;
- ✓ backup rotation interval and reserve size are variable;
- ✓ reserve turnover intervals are regular, and resource supply is unstable.

The basic condition for operating shovels and dump trucks with a regular uniform load throughout the year is to provide them with a constant supply of blasted rock at regular intervals (Figure 5).

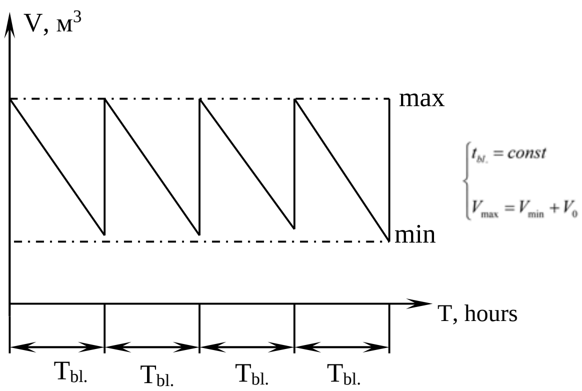

Fig. 5. Distribution of to be blasted the rock mass resources.

3. Result and discussion

In practice, the condition that the supply is regular when the supply time interval is regular is satisfied when the demand does not fluctuate over time. In our case, the number of equipment available may be uneven during the supply period due to maintenance and repair. Therefore, it is appropriate to consider the volume of the blasting rock mass or the volume of excavation and transporting resources between the minimum and maximum values required.

In this case, the volume of reserve to be prepared varies from the minimum to the maximum, depending on the demand for the supply (the blasting rock mass) in a given interval (the time between two consecutive blasts or the frequency of blast). In other words, the values of the maximum number of shovels to be available and the minimum number of resources to be prepared in the interval between the supply of the reserve are determined.

The time between the two blasts, or the reserve rotation interval, is given by the following formula, which is the average daily output of the shovels working on the bench and the ratio of the rock mass on the bench to be ready for excavation.

$$t_{bl.} = \frac{V_j}{Q^j_{sh.}} \tag{3}$$

where: j - the number of benches where shovels is in operation, V_j - the volume of the blasted rock mass on the j bench , m^3; $Q^j_{sh.}$ - average daily output of shovel, m^3/hour.

The number N_{year} of blasting per year, expressed in terms of the volume of the rock mass to be blasted during the year V_{year} and one time V_0, is expressed as follows.

$$N_{year} = \frac{V_{year}}{V_0} \tag{4}$$

where: V_{year} - the volume of the rock mass to be blasted per year, m^3; V_0 - volume of one time blasting, m^3.

The purpose of blasting is to distribute the blasting block N times a year in order to minimize equipment downtime. By reducing the number of blasting per year, it is possible to decrease downtime of equipment and to reduce the lost of productivity of equipment due to blasting work [7, 8]. However, as this increases the size of one time blasting, the cost of one-time blasting will increase, and the optimal number of blasting per year will be found at the lowest downtime of equipment and blasting costs.

To simplify the task of optimizing the number of blasting per year, or the volume of one-time blasting, we assume that the volume of blasting is regular for a given year. From this, it can be assumed that the average volume of one-time blasting is regular. Therefore, the linear model for optimizing the number of blasting per year by the cost of blasting operations can be formulated as follows, taking into account the deviation of the value of the resource allocation from the minimum to the maximum value and formula (4).

$$Z(V_0, t) = \frac{V_{\max}}{V_{\min}} = \left(N\bar{V}C_{bl.op} + \frac{V_{year}}{\bar{V}} T_{d.t} C_{l.d.t} \right) \tag{5}$$

where: N - number of blasting per year; $T_{d.t} = nt_i$ - duration of shovel's downtime due to blasting work; $C_{l.d.t}$ - loss per hour of shovel's down time, USD/hour; $C_{bl.op}$ - cost of blasting one cubic meter of rock mass, USD/m^3.

Based on the modeling equation (5) for optimizing the number of blasting per year, we can say that the actual blasting cost will increase directly by the volume of the blasting block, and the downtime of equipment will be a hyperbola type and located in the first quadrant of the coordinate plane.

Therefore, the volume of one tome blasting rock mass or solution of the equation is determined by the intersection of the straight line represented by the first addend of equation (5) and the hyperbolic represented by the second addend. Our task is one-dimensional because the blasting block for one time or resource distribution is a one-time allocation, and resource allocation is a multi-step static decision-making process. Instead, the decision and state vectors for each stage are one-dimensional. Therefore, let's optimize the linear model (5) by dynamic programming.

To do this, consider the number of blasting per year as a step in the decision-making process and let's transform the modeling equation expressed by equation (5) in the following order.

Divide the volume of the rock mass to be blasted or the annual reserve V_{year} required for shovels and dump trucks into V_0^i i=1, 2, ..., N sub-sets of one-time blasting. The cost $z(V_0^i)$ of the resource or cost of the blasting rock mass, the downtime (t) of the equipment and downtime loss $z(t^i)$ are attended for each V_0^i.

Therefore, the cost of blasting during a given year can be given by the sum function:

$$Z(V_0^1, t^1, \ldots V_0^N, t^N) = \left(\sum_{i=1}^{N} z(V_0^i) + \sum_{i=1}^{N} z(t^i) \right) \tag{6}$$

and the amount of resource to be used, or the volume of rock to be blasted per year, is expressed by the formula:

$$V_{year} = \sum_{i=1}^{N} V_0^i \tag{7}$$

and the following condition are met.

$$V_0^i > 0 \tag{8}$$

Therefore, the task of optimizing the number of blasting per year is determined by a mathematical model expressed by the following equation with the objective of minimizing blasting costs.

$$Z(V_0^1, t^1, \ldots V_0^N, t^N) = \left(\sum_{i=1}^{N} z(V_0^i) + \sum_{i=1}^{N} z(t^i) \right) \to \min \tag{9}$$

$$V_{year} = \sum_{i=1}^{N} V_0^i, \ V_0^i > 0 \tag{10}$$

The first addend of equation (9) is expressed the volume of the rock mass to be blasted at one time and the cost of the blasting rock mass for 1m^3. Loss of production due to downtime of the shovels' park is expressed as the number of not working machines and their downtime. So, equation (9) can be written in the following form.

$$Z\left(V_0^1, \mathrm{t}^1, ...V_0^N, \mathrm{t}^\mathrm{N}\right) = \left(\sum_{i=1}^{N}\left(V_0^i C_{bl.op}\right) + \sum_{i=1}^{N}\left(nt_i C_{l.d.t}\right)\right) \to \min \quad (11)$$

where: n – the number of not working shovelss during i blasting due to blasting work; t_i - duration of i blasting work or duration of downtime time for one machine due to blasting; - loss of shovel's downtime for per hour, USD/hour; V_0^i - volume of rock mass to be fragmented during i blasting work, m^3; $C_{bl.op}$ - cost of blasting for one cubic meter of rock mass, USD/m3.

At the beginning of the resource allocation, i at the beginning of the process, the amount of resources allocated is $V_0^i = 0$, and at the end of the allocation, $V_0^i = V_{yeat}^i$. Therefore, since the state space is one-dimensional, as described above, there will be only $s_0 = 0$ and $s_N = V_{year}$ at the beginning and end of the distribution, and during the distribution the state s_0 will be transformed to the s_N state under optimization conditions. We divide the interval [0, N] into sub-intervals E, or construct decision sub-spaces, to select the amount of work to be done in a single blast.

Dividing the interval [0, N] into sub-intervals will make the problem discrete, and the problem will be easier if we choose the same length Δ of the interval as shown in Figure 2. The length of the interval can be $\overline{V} = \frac{V_{\max} + V_{\min}}{2}$ as shown in Figure 2.

Thus, the modeling has been developed to manage the supply of shovels and dump trucks with the fragmented rock mass by dynamic programming, which allows reducing the downtime due to blasting of all mining equipment, thus ensuring the lowest cost and normal operation of loading, transportation operations. Accordingly, the above-explained task for determining the blasting period is a significant solution to determine how the process interacts with the excavation and hauling operations. This ensures that the digging and transporting process can be operated efficiently at the lowest possible cost.

4 Conclusions

According to a study at the Erdenet open-pit mine, as the mine's capacity enlarges, the stripping, extraction, and the volume of blasting work rises each year. As a result, equipment downtime increases, and performance losses increase. In particular, it has been defined that the downtime of the mining equipment increases linearly as the volume of the rock mass to be blasted per year increases.

Therefore, the study shows that the problem can be completely solved by managing the volume of one-time blasting and the time between explosions.

By optimizing the time between blasting through dynamic programming, it is possible to reduce the direct and indirect costs associated with blasting.

[2]National University of Water Management and Environment Management, 11 Soborna Str., Rivne, 33028, Ukraine

Abstract. Ventilation when driving roadways is one of the most important considerations in coal underground mines. Ventilation efficiency depends on fan performance and ventilation ducting system. In recent years in Vietnam, ducts have often been produced domestically. However, parameters of the duct as duct leakage, duct resistance for designing auxiliary ventilation system are referenced from abroad handbook. This lead to inaccurate design results and needs to adjust efficiency of auxiliary ventilation during driving roadways. Determination of duct resistance; air leakage in ducting system have been undertaken. The research result has been used to optimize the auxiliary ventilation system.

Introduction

The auxiliary ventilation is carried out by bringing air to the work fronts, as the track is advanced, the amount of air that reaches the front gradually decreases due to the greater resistance of the conduit and the increase of the leakage [1]. Complete elimination of air leakage from, or to the duct system is impossible due to the duct quality and numerous joints in the duct system [2].

In Vietnam, studies on an auxiliary ventilation mainly aimed at finding solutions to improve the ventilation efficiency when mining roadways driven in coal mines. The number of these works is not much, especially there is no research on the resistance and air leakage in ducting being used in coal mines. Up to now, for designing auxiliary ventilation system, duct parameters were referenced from foreign handbook. In addition, these data are published long time ago, while at present, materials as well as duct technology are much different from before that affects the optimization of the auxiliary ventilation system.

Therefore, investigation of air leakage and resistance of auxiliary ventilation ducting in underground mine in Quang ninh has been undertaken. The research result is necessary for optimizing the auxiliary ventilation system.

The parameters of the duct as duct resistance; air leakage play an important role in the design of the auxiliary ventilation.

1 Measurement of duct resistance used in coal underground mines

1.1 Fundamentals of duct resistance

Air leakage through in ducting system flows in turbulent flow mode [3]. In turbulent flow mode, airflow energy loss for overcoming viscosity of the air due to turbulent vibrations, so this level of energy loss is much higher than that in laminar flow. Pressure loss due to frictional resistance in a round duct is determined by:

$$\Delta P = H = \lambda.\frac{L}{D}.P_v = 32.25.\alpha.\frac{L}{D}.\rho v^2 \qquad (1)$$

Where:
ΔP: Pressure loss (head loss) due to frictional resistance in duct L long, mmH_2O;
P_v: Velocity pressure in duct, mmH_2O;
λ: Friction coefficient, dimensionless coefficient;
L: Distance between two cross sections of duct, m;
α: Friction factor for the duct, $KgF.s^2/m^4$;
D: Diameter of the duct, m;
ρ: Air density, kg/m^3;
V: Average velocity at the duct cross-section, m /s.

A relationship between pressure loss and friction factor in duct is given by:

$$\frac{H}{L} = \frac{P_1 - P_2}{L} = 65.4.\frac{\alpha}{D}.\frac{\rho}{2} \qquad (2)$$

Where:
P_1: Pressure of air at section 1
P_2: Pressure of air at section 2

However, at present, there is not expression for calculating friction factor α. It has been determined experimentally.

One of the most basic ventilation equations describes a relationship between pressure loss and airflow volume in a duct is $H= \Delta P= R.Q^2= R.(v.S)^2$ [4] so that friction resistance in ducting system can be obtained by the following equation:

* Corresponding author: dangphuongthao@humg.edu.vn

$$R = \frac{H}{v^2.S^2} \qquad (3)$$

Where:
R: Friction resistance, kμ;
S: Cross sections of duct, m^2:

From equation (3), the specific resistance - r and friction factor of the duct can be found:

$$r = \frac{R}{L} \text{ And } \alpha = 0.25.\frac{H.D}{v^2L} \qquad (4)$$

2 Experimental procedures

Laboratory set-up. Experimental model for determination of duct resistance was set up at Institute of Mining Science and Technology - Vinacomin (IMSAT), Uong Bi, Quang Ninh.

Fig. 1. Experimental apparatus for determination of duct resistance.

For the model to determine the resistance of the duct with diameter D = 0.6m and air flow Q = 3.4 m^3 / s, the velocity in the duct

$$v = 3.4:\left[\pi * \left(\frac{D}{2}\right)^2\right] = 12.02 \ m/s$$

Reynolds number:

$$R_e = \frac{v.D}{\nu} = \frac{12.02 * 0.6}{14.4 * 10^{-6}} = 500833$$

Where: ν is the viscosity coefficient of the air ν = 14.4 x 10^{-6}

Duct length between two cross sections of duct section must be satisfied:

$$L = 0.639 * R_e{}^{0.25} * D = 10.2 \text{ (m)}$$

Thus, for the duct with diameter D = 600mm, duct length is set 15m. Measurements were conducted on a fabric duct of 600mm diameter, 15 m length.

Fig. 2 shows the schematic diagram for determination of duct resistance.

Fabric duct is connected directly to rigid steel ducting and carried as straight in the horizontal direction.The ducting system must be stretched tight during installation. Hence, the pressure loss on the ductwork is caused by frictional resistance [5]. Since the duct from PL_1 to PL_2 has no joints, local resistance does not appear.

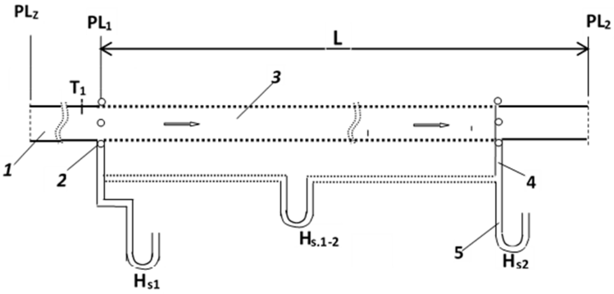

Fig. 2. Schematic diagram for determination of duct resistance: 1 - rigid steel ducting; 2 - holes for measurement; 3 - flexible fabric ducting; 4 – pitot-tube; 5 - U tube.

Velocity v at the center of each section was measured by a pitot tube. The cross sectional area of the duct was equally divided into four areas, 16 points traverse as shown in Fig. 3 [6].

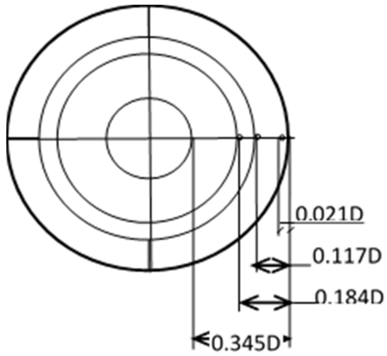

Fig. 3. Diagram position of traverse points in a circular measurement section for 4- area, 16 point traverse.

The average velocity V in the duct was calculated from the arithmetical mean value of v. At the same time, the pressure difference between the pressure PL_1 and PL_2 was measured and related with the average velocity V [7].

From that the average velocities at the measuring of the pressure drops along the ducts can be obtained.

Fig. 4 shows cross sectional area for pressure measurement and pitots in practice.

Fig. 4. Cross sectional area for pressure measurement and pitots.

3 Test results

Experimental data for determining duct resistance R, specific resistance r and friction factors are shown in Table 1. Average values of the resistance R, specific resistance r and friction factors calculated for test ducting are as:

$$\bar{R} = 4.041\ \text{k}\mu;\ \bar{r} = 0.0269\ k\mu.m^{-1};$$

$$\bar{\alpha} = 0.00030\text{KgF}.s^2.m^{-4}$$

Table 1. Experimental data and results for determining duct resistance.

Measurement	1	2	3	4	5
Airflow Q, m³/s	7.33	7.42	7.42	7.42	7.43
Pressure at section PL_1, Pa	785	784	781	780	777
Pressure at section PL_2, Pa	558	569	553	564	555
Resistance R, kμ	4.224	3.902	4.138	3.921	4.0201
Specific resistance r, kμ/m	0,02816	0,02602	0,02759	0,02610	0.02680
Friction factor α KgF.s²/m⁴	0.00034	0.0031	0.00033	0.0003	0.00032

The values for the measured friction factor is small compare with published values calculated by others as shown in Table 2 [8]. However, the measured friction coefficient (0.0003 kgF.s^2 / m^4) is much smaller with the value using the auxiliary ventilation design in Vietnam (0.00048 kgF.s^2 / m^4).

Friction factor depends on the smoothness of the duct material, diameter as well as the tension level of the ducting system.

Table 2. Quoted friction factors for flexible duct.

2. Estimation of air leakage of duct used in coal underground mines

Level of air leakage is mainly influenced by the following factors: total length, diameter of the ducting and airflow in the ducting system. The experimental data are made on 0.6 m diameter ducts over sections of ducts installing towards the working face in actual field conditions in Quang Ninh coal mine as shown in Tab.3. A conceptual prediction model has been proposed based on experimental data at Quang Ninh Coal mine [9].

$$p = f(L, Q) \qquad (5)$$

Let p, L and Q represent leakage coefficient, duct length and quantity of airflow in the ducting system respectively. It is assumed to express p in the form:

$$\ln(p-1) = lnc + b_1 lnL + b_2 lnQ \qquad (6)$$

Where: p : Leakage coefficient;
L: Duct length, m;
Q: Quantity of airflow in the ducting system, m^3/s;
lnc, b_1, b_2, constants.

Each set of data: ln (p_i), ln (L_i) and ln (Q_i) under given data – duct diameter, with i=1, 2…n.
With ducting length L_i, the quantity of airflow in the ducting system Q_i is measured; the air leakage coefficient p_i is calculated as $p_i = \frac{Q_0}{Q_i}$;
Where: Q_0 the quantity of airflow beyond the fan, m^3/s;
Q_i the quantity of airflow reaching the end of the ducting length - L_i.

Table 3. Experimental data for the duct of 0.6m diameter.

Q(m³/s) / L(m)	1.5	2	2.5	3	3.5
100	1.022	1.025	1.028	1.030	1.032
200	1.081	1.091	1.100	1.108	1.115
300	1.173	1.195	1.214	1.230	1.245
400	1.296	1.333	1.365	1.394	1.420
500	1.448	1.505	1.554	1.597	1.636
600	1.630	1.709	1.778	1.839	1.894
700	1.839	1.945	2.037	2.118	2.192
800	1.455	2.213	2.330	2.434	2.529
900	2.341	2.511	2.657	2.786	2.904
Q(m³/s) / L(m)	**4**	**4.5**	**5**	**5.5**	**6**
100	1.033	1.035	1.037	1.038	1.040
200	1.122	1.128	1.133	1.139	1.144
300	1.259	1.272	1.284	1.296	1.307
400	1.443	1.466	1.486	1.506	1.524
500	1.672	1.706	1.737	1.767	1.795
600	1.945	1.000	2.036	2.078	2.117
700	2.259	2.322	2.381	2.436	2.489
800	2.615	2.696	2.771	2.843	2.910
900	3.012	3.113	3.207	3.295	3.379

Let y_i, x_{i1}, x_{i2} and b_0 represent ln (p_i -1), lnL_i, lnQ_i and lnC respectively. Equation above can be rewritten:

$$y_i = b_0 + b_1 x_{i1} + b_2 x_{i2} \qquad (7)$$

Least-squares regression is to fit these experimental data that minimizes the sum of squared residuals [10]:

$$\sum_i^n e_i^2 = \sum_{i=1}^n \left(y_i - b_0 - \sum_{j=1}^2 b_j x_{ij}\right)^2 \qquad (8)$$

Take derivatives with respect to the model parameters b_0, b_1 and b_2 set them equal to zero and derive the least-squares normal equations that our parameter estimates b_0, b_1 and b_2 would have to fulfil.

Normal equations of two independent variables can be written in matrix form as:

$$\begin{vmatrix} \sum_{i=1}^n x_{i1}^2 & \sum_{i=1}^n x_{i1}\, x_{i2} \\ \sum_{i=1}^n x_{i1}\, x_{i2} & \sum_{i=1}^n x_{i2}^2 \end{vmatrix} \begin{vmatrix} b_1 \\ b_2 \end{vmatrix} = \begin{vmatrix} \sum_{i=1}^n x_{i1} y_i \\ \sum_{i=1}^n x_{i2} y_i \end{vmatrix} \qquad (9)$$

Solve the above matrix to obtain the regression coefficients. Therefore, the air leakage coefficient for the duct of 0.6m diameter can be obtained based on data at Quang Ninh mine:

$$p= 1 + 3.5078.10^{-6}.L^{1.865}Q^{0.4135} \qquad (10)$$

Use the F-test can evaluate Pro (F) = 0.0000 with significance level is 0.5. This low a value would imply that the regression parameters are nonzero and the regression equation does have some validity in fitting the data.

Conclusion

The resistance and air leakage of the duct depends on many factors, in which the ducting material and size play an important role.

For designing auxiliary ventilation system, duct parameters were referenced from foreign handbook that causes results in lack of confidence.

Factors such as duct size and diameter, aerodynamic parameters in duct airflow influence on duct air leakage.

A conceptual prediction mode can be determined duct air leakage based on the experimental data at Quang Ninh mine. Also, the research result has been used to optimize the auxiliary ventilation system. Optimization of the auxiliary ventilation system can save cost and energy.

Authors would like to thank to Quang Ninh coal companies for the support with site access and field investigation. This work was financially supported by Hanoi University of Mining and Geology.

Defining the information flows for DLT of a transport company in the mining industry according to the criteria for sustainable development

Teodora Hristova[1,*], *Dimitar* Anastasov[2], and *Zdravets* Evtimov [2]

[1]University of Mining and Geology “St. Ivan Rilski”, Department of Electrical Engineering, 1700 Sofia, Bulgaria
[2]University of Mining and Geology “St. Ivan Rilski”, Department of Mining of Mineral Deposits, 1700 Sofia, Bulgaria

Abstract. The application of information technologies leads to the improvement of the companies’ production parameters in each sector according to the criteria for sustainable development. Naturally, in order to achieve efficiency, they must be tailored to the specifics of the industry, in this case the mining industry. The article proposes a methodology for the introduction of Distributed Ledger Technology (DLT) for the transport information flow at a mining company. Based on the chosen organizational structure, the participating actors and the data they share, the information channels are determined. According to the necessary rights of the participants to modify the transactions and the number of channels of the transport information flow, a consensus mechanism Practical Byzantine Fault Tolerant and the so-called smart contract have been chosen. Different DLT platforms are analyzed. Hyperledger Fabric was selected as an appropriate platform in order to ensure the continuity of the system, the asynchronous control of the various channels and the ability to include different actors.

1 Introduction

In the second half of the XXth century there is an increase in population along with global economic growth, which is associated with excessive, intensive and uncontrolled use of natural resources [1]. In order to meet the needs of present and future generations on the Earth, the Brundtland Commission published a report on the sustainable development in all areas of life and human activity [2]. This means that the implementation of measures in one area must not be at the expense of deteriorating performance in another area. In addition, the measures taken should not be temporary initiatives, but long-term management decisions that have a positive effect on all areas affected.

Dubinski defined the following main pillars of sustainable development in the mining sector [1]:

- technical and economic activities for continued economic growth;
- introduction of ecological measures for environmental protection and appropriate use of natural resources;
- social events to improve working conditions, care for employees and personal development in the mining community.

With the growth observed in the quantities of extracted minerals from ancient times to present days, the main aim of the economic and technical means is the reasonable acquisition of natural resources. Therefore, according to the first pillar of economic growth, it is recommended to undertake measures for long-term sustainability in terms of planned production and sales volumes, which is directly related to the improvement of the technical means for extraction and processing of mineral resources.

In recent years, measures have been taken worldwide to reduce harmful emissions of waste products into soil and water generated by the mining, chemical and pharmaceutical industries [3, 4]. The reclamation of the excavated land masses and the improvement of the working conditions with reduced amounts of industrial accidents, dust and noise are considered with regard to the environmental measures [5]. The reduction of industrial accidents and occupational diseases, due to the presence of harmful substances are the main target for improving the working conditions, typical not only for the mining, but also for the chemical industry and agriculture. They have the highest share in countries with low innovation potential and in developing countries [6].

According to [7], the measures become effective with government support and this is proved by the enactment of many directives for reclamation and waste recycling [8, 9] from the mining activities, reduction of carbon emissions, efficient use of energy sources, etc.

At the same time, measures for staff training with new technologies, introduction of leisure activities, practices for the development of the innovative concept "Shared values", the “Got it” system for collection, evaluation and implementation of ideas from the employees, communication programs with the community and others are recommended [10, 11].

* Corresponding author: teodora@mgu.bg

An essential element for achieving the recommendations for sustainable development is the life cycle assessment (LCA) for each production process.There are two aspects with regard to the mining industry [12]. On the one hand, this is the impact assessment of the products from the activity on the environment and comparison of the indicators of different types of mining per kilogram. On the other hand, the mining industry can use LCA to assess the impact of its activities on nature in order to improve the technology.

2 Sustainable development and information technology

The introduction and evaluation of production activities according to the criteria for sustainable development can be done through new technical means for data management and processing, related to the complexity of the links among the individual sectors in each company. The implementation of an information system would not only lead to traceability and security of information flows, but would make progress in increasing the innovation potential in the mining sector. At the current stage of production, Bulgaria is the only EU member state with the lowest innovation index [10]. Therefore, process management, assessment of the state and raising the innovation index would not be possible without modern information technologies.

The introduction of information technologies in industrial production is associated with positive and negative aspects. Initially, financial resources, training, infrastructural changes, and sometimes even layoffs, recruitment or retraining of staff are needed. On the other hand, remote control, improved security and accountability, traceability of the information flow, etc. could be achieved by using them.

Firstly, the implementation of DLT implies security in data transmission, which will first increase trust among partners and therefore improve the working atmosphere. Secondly, it will contribute to the efficient consumption of fuels and resources, which will have an economic effect. Thirdly, the automatic sending and archiving of reports increases the accountability and traceability of all documents to the point of impossibility of theft by third parties.

Naturally, each new technology is built on the basis of a previous one. For example, when upgrading databases with DLT, it was found that the information could be compared and evaluated. On the other hand, data are shared among nodes more slowly compared to the SCADA system, which is designed to manage production processes. The advantage of DLT is the security, non-modifiability and traceability of the transmitted data, which makes it a suitable system not for managing production processes, but for sharing confidential data among commercial, production and regulatory organizations. With the implementation of this new information technology, different communication channels appear among subjects which exchange data of mutual interest.

Therefore, to assess production support measures according to the criteria of sustainable development, DLT is suitable for sharing information flows in mining enterprises. These are electricity, production, waste, transport, security. As a new technology, whose legislation is from 2019, it is necessary to develop an algorithm for implementation, definition of information channels and definition of the attributes in the blockchain for the described sharing channels. At present, such do not exist yet.

The purpose of this article is to determine the stages of the method for implementing DLT and achieving improved communication by clearly defining the communication channels and the type of transmitted information for the transport sector in a mining enterprise.

3 Methods

As a new information technology, the regulations for blockchain and DLT are respectively from 2017 and 2019, which necessitates a brief definition of their functions, advantages and disadvantages. The methods for building DLT are based on different platforms - Ethereum, Hyperledger Fabric, Corda and others. These platforms differ according to the method of data transmission, the rights of the participants to modify the data, the transmission speed, etc.

Given the history of DLT, the main research and development of the above-mentioned platforms are for cryptocurrency management [13, 14], trade and economic flows, as well as their protection against cyberattacks [15]. In recent years, there has been a study on the implementation of the technology in ticket sales in rail transport [16] and fleet management.

With the isolation due to the COVID-19 pandemic, the real applications of the technology are increasing.The already implemented and working solutions prove the possibilities for tracking cryptocurrencies to various commercial products. Although the DLT regulation is from 2019, there are already successful commercial applications such as tracking the origin of eggs from Farmers Hen House via QR shared codes, authentication of COS sweaters via My Story™ labels by H&M and VeChain [17, 18]. The most visible effect is to the transparent and unmodifiable tracking of supplies of medicines and food, encompassing the companies Deloitte, Maersk, the World Bank and the World Food Program [19].

In the industry, as a representative of the transport sector, Volkswagen has implemented DLT to track parts and origins of materials for the manufacture of batteries for electric vehicles [20], management and settings of cars in the construction of smart cities [21]. An analysis of the platforms shows that the Hyperledger Fabric is preferred in the transport sector, as can be seen from the website [22].

At a round table in Toronto, leading IT and mining experts have identified the following streams as leading directions for the implementation of DLT in the mining industry [23]:

1. Management of the financial resources in communication with banks and suppliers;
2. Communication with state institutions;
3. Human resources management;
4. Repair system when reporting accidents.

The management of vehicle traffic is not explicitly mentioned, but haulage is a major activity in large and distributed mining companies and area 4 - the repair and accident system is part of it. For this reason, the article is aimed at defining the channels of the transport information flow and the shared data.

In order to define the stages for implementing a blockchain-based DLT for transport channels for sharing, these concepts have to be defined first.

Since the organizational structure of each enterprise is the framework for reporting the relationships in an organization, the first step of the proposed methodology is to consider the main organizational structures. The values for measurement and transmission to the respective actors are determined according to the structure of the organization and with regard to the selected information flow. The number of channels for the respective information flow is then determined, as not all data are transmitted to all participants in a given communication scheme.

In order to achieve consensus, decentralization and equality in data transmission, it is necessary to define a consensus mechanism. The following is a design for smart contracts to set sharing rules and a platform selection.

4 DLT and Blockchain

DLT is a decentralized database containing information visible to all actors in real time. The system allows the sharing of the necessary information among the network's participants through the respective synchronization. To achieve security, the data is encrypted and changes by each participant are authenticated with their own key. On different platforms, participants' rights to modify the data may be different, but the common denominator is that once modified, the data cannot be deleted. Thus, the system ensures unmodifiability, traceability and transparency of information flows [24].

The blockchain [25], as the name suggests, is a chain of blocks (codes) connected by cryptographic algorithms, containing identical information. The management of transactions in the network is through a consensus mechanism that validates the allowed transactions when adding them to a block. This is a method of authenticating and validating a value or transaction without the need for explicit trust or reliance on a central institution, i.e. on a third party. Thus, the recommendation for economic optimization of expenditures according to the criteria for sustainable development is implemented by eliminating the need for an intermediary and giving the possibility to each participant to be both a provider and a user of data.

The transmission and recording of the information among these participants in the blocks takes place after its verification as genuine through the so-called smart contracts.

The choice of blockchain, smart contract and consensus mechanism depends on the parameters of the organizational structure, the rights of the participants to modify the transactions, the number of information flow channels and the type of information flow.

It has been established in previous studies that the information flows in the mining industry are the supply and reporting of fuel or repair equipment, the monitoring of energy parameters by shifts and departments, the quantity and quality of the extracted or processed product, the monitoring of emissions [26]. These information flows include data from the measures and laws introduced in recent years to reduce harmful emissions, optimize production, introduce new technologies for extraction and transport.

The development of information technologies has necessitated a remote or GPS system for tracking the routes of vehicles. In addition, methods are being developed to study their technical serviceability or efficiency. To carry out the above-mentioned activities, specialized information management is required [27]. In order to improve the efficiency of vehicle management in a mining company through DLT, the transport sector will be analyzed. Due to the differences in mining companies, the options are many and specific, but the information flow in all cases depends on the organizational structure of the company, which requires a brief overview of the main structures.

5 Organizational structure

Different organizational structures are characteristic for the mining industry and they depend on the functional peculiarities of production, the history of the organization, and the geographical features. Since mining production includes various activities such as extraction, processing, reclamation, there are different types of companies - Ltd., JSC, holding, industrial group and outsourcing. All these companies are characterized by a hybrid type of organization, which combines functional and geographical type of structure.

5.1 Holding

The holding company is a business entity that combines the assets of various subsidiaries and performs supervisory functions. It is characteristic that it generally does not carry out specific business activities and does not actively participate in the management of the day-to-day operations of its subsidiaries. Therefore, this type is not considered in the present study.

5.2 Industrial group

The industrial group includes companies that can work in various fields - construction, consulting, mining, energy, environment, haulage, security, etc. The companies in the industrial group can interact among themselves, but they can also have projects with external companies and partners.

5.3 Outsourcing

Outsourcing is the business practice of hiring a firm outside the company to provide services or create goods that are traditionally done internally by the company's own employees and staff. It was first recognized as a business strategy in 1989. This way of transferring tasks is undertaken as a cost reduction measure. This is a method for companies to allocate resources where they are most efficient, according to the criteria for sustainable development. It helps to preserve the nature of free market economies worldwide. This way of transferring tasks allows the companies to focus on key aspects of the business, allocating less critical operations to external organizations.

In the present study, the communication channels in a given outsourcing company are defined, because in the communication among companies it is possible to reduce the security in data transmission, to lose trust among the partners. Therefore, a need for protection arises when transmitting confidential data without disrupting the communication among the suppliers and the company, etc. The implementation of DLT will further facilitate the efforts of the legal teams of the companies when signing contracts in which the type and the way of sharing confidential data must be precisely mentioned.

With the implementation of Internet technologies, in all companies, amorphous parts of the structure have emerged, which can lead to confusion in the management and executive staff. This further reaffirms the need for a DLT, which will clearly define the ways in which the information required is transmitted to each participant.

The object of analysis is the transport information flow, as the communication channels proposed in the article can be modified according to the parameters and organizational features of a specific production process. They can also be used by smaller companies.

6 Main parameters

The implementation of each database as well as DLT begins with defining the transmission data [28]. For a transport company working in the mining sector, it is necessary to differentiate the data according to the actors involved.

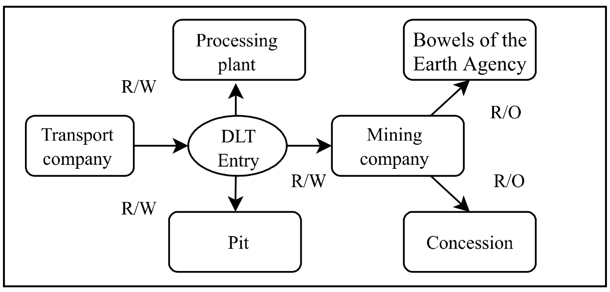

Fig. 1. Scheme of production.

The actors interested in these data are the Pit, the Processing Plant, the Transport Company, the Mining Company. It communicates and shares data with state-owned companies, agencies and regulatory bodies in accordance with the legislation. It is obvious that there are many participants and sharing all the information would complicate the work of each of them. Therefore, the following information flows are defined for the transport sector:

1. The amount of ore. In this information flow among the participating companies are shared data on the parameters: amount of development, amount of ore transported, number of courses of vehicles, fuel consumed, stope (working face). The actors interested in these data are the Pit, the Processing plant, the Transport Company, the Mining Company. They all share the measured values and confirm the received records. The mining company sends official reports to the Bowels of the Earth Agency and the concession, which only accept these data, i.e. their rights are read-only. The conceptual model for communication in this case is visualized in Fig.1.

2. Technical condition. The technical condition of the vehicles of the transport company depends on the working hours, the number of courses of full vehicles, the number of courses of empty vehicles, the distance traveled. In the presence of electric vehicles, the company may have implemented a system for remote diagnostics according to the temperature of certain parts or other parameters. In order to reduce carbon emissions [11], the share of electric vehicles in all sectors of production is expected to increase [29], and the information flow can be supplemented with parameters such as tire condition, battery condition, battery voltage of the individual vehicles, charging time, number of charging cycles, LCC, management or optimization of PV renewable source for charging [30] and etc. Information flows in the management of electric vehicles are not discussed in the article. The data about the technical condition are transmitted by the transport company to the repair company and to the mining company. The conceptual model for communication in this case is visualized in Fig. 2.

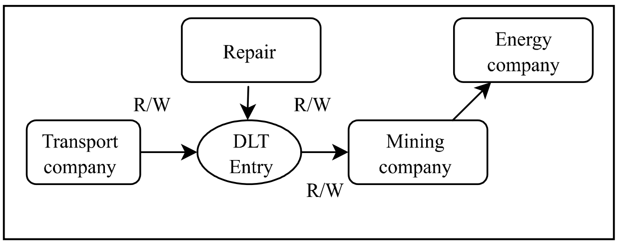

Fig. 2. Scheme of repair flow.

3. Delivery of repair equipment and parts. Every company has repair parts in stock, but each repair is also related to the delivery of new ones. In this information flow, the main data are the number and type of parts in stock and the number and type of parts to be ordered. Therefore, when registering a repair event, the transport company contacts the repair company and the mining company. For its part, the repair company contacts all the

suppliers. It has information about the technical condition of the fleet and can pre-order the elements necessary for maintenance. The conceptual model for communication in this case is visualized in Fig. 3.

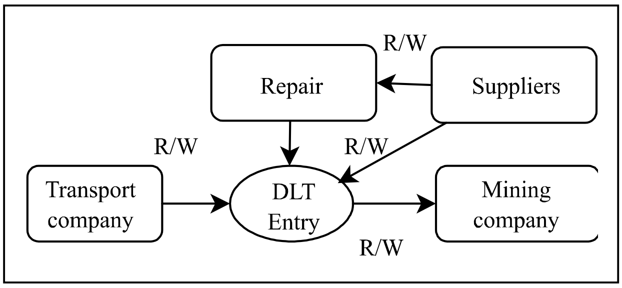

Fig. 3. Scheme of suppliers.

4. Financial flow. The transport company has employees and a fleet. It pays salaries, insurances, trainings to the employees, and buys fuel and energy for the fleet, takes over the repairs. The conceptual model for communication in this case is visualized in Fig. 4.

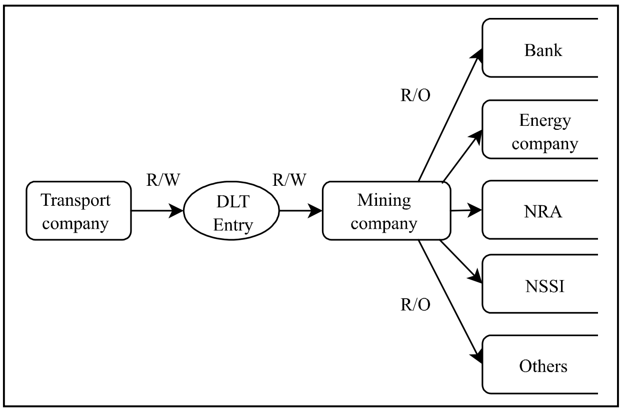

Fig. 4. Scheme of finance flow.

In Figure 4, The Mining company submits data to all external organizations, and they only have the right to view it.

The funds for the financial servicing of the fleet and the employees are received by the Mining Company after reporting on the work performed. In addition, the Transport Company submits a report about its expenditures to the Mining company, which is in contact with the government agencies (National Revenue Agency (NRA), National Social Security Institute (NSSI)), the electricity distribution company and the regulatory authorities.

The only organization that can verify the information sent is the electricity distribution company. This happens when monitoring the parameters of electricity, for example if the transport company has a large number of electric vehicles, which is not reported in the scheme. If it is necessary to halt the activity of the mining company, which is a big consumer of electricity, it warns the electricity distribution company. The same process is repeated at start-up, with the electricity distribution company allowing the start-up of a mining company's activity. If it is necessary to monitor the parameters of electricity, it is necessary to make a separate scheme of information flow related to the quality of electricity, which is among the future tasks of our team.

The study is useful for the mining industry, but the defined flows can be applied to trace hazardous substances in the chemical and pharmaceutical industries, hospitals [4], automotive [20], engineering, agriculture, etc. The results of the study can be applied in other activities after the identification of the following flows:

Characteristics - composition of the flow, source, purification (treatment), discharge - qualitative and quantitative composition, time;

The Supply chain – spare parts, fuel and lubricants – quantity, supplier, quality etc.;

Maintenance – regular vehicle checks, distance travel, tracking of the lifetime engineering cycle;

Documents flow – tamper resistance, redundancy, non-repudiation, tracking etc.;

Operational data – drivers working shifts, quantity of raw material transported, regular vehicle position checks.

7 Consensus mechanism

The data from the defined information flows are validated when added to a block and transmitted to the network of ledgers by a consensus mechanism. It is not necessary for all participants to see all the information in this structure, which is one of the main criteria for choosing a consensus mechanism. In the event of a software issue or another problem in one of the communication channels, it is necessary for the system to continue to operate, without requiring high speed data sharing.

Analyzing all these features for the case under consideration, the suitable consensus mechanism is the Practical Byzantine Fault Tolerant, in which the management is centralized and carried out by the Mining Company. This mechanism allows a clear definition of the participants without excluding the addition of new ones, for example when signing a contract with a new supplier. It provides protection against Byzantine faults [31]. Although Hyperledger Fabric (v 2.2) ordering service is still not ready with PBFT implementation (RAFT CFT is used), it is marked as the milestone for next releases [32, 33]. In addition, its advantages are that there are no initiatives on the nodes, there is no requirement of hash power.

8 Smart contracts

The business logic of the channel is implemented by Smart Contracts, which are computer programs or frameworks that automatically take over tasks and responsibilities in the shared ledger. This is a computer code that recreates the contractual logic of the real world. Acting at the node level under a specific regulation among the participants and the proper functioning of the principle of consensus, they validate and record the shared data. Examples of such platforms are Ethereum, Hyperledger Fabric, etc. The following table 1 provides a comparative analysis of the main platforms.

8.1 Ethereum

Ethereum uses the Proof-of-Work consensus algorithm, in which all participants must reach a consensus on the order of transactions. It lacks confidentiality because any user can see any type of information, which is inapplicable in this case.

Table 1. Comparative analysis of the main platforms

DLT platform	**Type**	**Block creation time**	**Energy consumption**	**Consensus**
Bitcoin	public	10 min.	high	PoW
Ethereum	public	15 sec	high	PoW
EOS	public	0,5 sec	no data	DPoS
Cardano	public	20 sec	no data	Ouroboros
Fabric	private	0,5-2 sec	very low	Modular
Sawtooth	private	no data	very low	PoET (Intel SGX)
IOTA	private	settings	very low	Tangle
Multichain	private	settings	very low	Distributed consensus
Corda	private	0,5 – 2 sec	very low	Notary nodes
Walton-chain	public and private	30 sec	low	WPoC

8.2 Corda (R3 CEV)

Corda was created for financial institutions, with participants agreeing in advance on a set of rules. The Node-to-Node (N2N) consensus algorithm is used, which allows control over the access to the network records. It is suitable in case of a request of a regulator to make a detailed and comprehensive check of the transactions in the network. Achieving security and indisputability of the records is related to the requirement for all participants to be online. For the mining sector, the use of a consensus mechanism suitable for the banking sector is inappropriate.

8.3 Hyperledger Fabric

It is designed for corporate use and all peers maintain one ledger for the channel to which they are subscribed (channels can be more than one). However, unlike other blockchains, in Hyperledger Fabric not all nodes are the same and this arises as a result of the different roles of the representatives of the organizations in the network, which is appropriate for the considered information flow - fleet management.

Hyperledger Fabric allows each network member to identify its representatives, which are configured in appropriate cryptographic materials, such as a Certificate of Identity. There is an opportunity to enter individual settings and preferences when building solutions for shared ledgers, which allows multi-channel communication of the transport company when sharing essentially different information flows.

The main shortcoming which is documented is the requirement to develop a list of participants in the network and give them access through membership of a centralized institution. In this case, however, this is an advantage because it coincides with the peculiarities of the considered organizational structure of an outsourcing mining company. Therefore, for the analyzed information flow, this has already been done and Hyperledger Fabric is the appropriate platform. The constraints of the research are the usage of non-permissive DLT platform Hyperledger Fabric in the management of the information flow in a transport company in the mining industry.

The implementation of DLT to the mining industry is an even more controversial issue. We were unable to find research papers on the application of DLT in the mining industry. Examining the maturity of technology, there is a rapid development of the legislative and regulatory framework, as well as the number of companies that have implemented the system. However, this involves costs, organizational changes, staff training, an increased attack area and the need for new cyber defense methods [15]. Despite Deloitte's estimates that by 2025, about 10% of global GDP will be based on blockchain structures [34], categories of standards applicable to the DLT and the blockchain have not been developed yet. These are framework standards, technology standards, platform-specific standards and industry-specific standards. The above-mentioned shortcomings are typical not only for DLT, but also for most information systems for data transmission.

Despite these limitations in the implementation of DLT as an ever-changing legal framework, the high electricity costs for data transactions, the need for staff training and more, the team believes that applications will increase worldwide. According to [35] DBMS should provide:

- Data storage, retrieval and update;
- User accessible catalog or data dictionary describing the metadata;
- Support for transactions and concurrency;
- Facilities for recovering the database, should it become damaged;
- Support for authorization of access and update of data;
- Access support from remote locations;
- Enforcing constraints to ensure data in the database abides by certain rules.

Thus, data confidentiality, processing logic, irreversibility, non-repudiation, and data redundancy aren't any part from an initial DBMS fully fledged solution. However, they can be partially achieved with additional explicitly added IT procedures which are out of scope of our research. DLT solutions implicitly add an additional layer that provides the described missing properties on the top of the DBMS solution.

9 Conclusions

According to the criteria for sustainable development in the mining sector, fleet management through a new information technology has been proposed. The article presents an algorithm for implementing DLT in an outsourcing company for sharing data by a transport company.

According to the methodology, the directions for sustainable development of the mining sector were

https://doi.org/10.1051/e3sconf/202128008003

initially clarified and the peculiarities of the organizational structure of an outsourcing mining company were analyzed. In order to build information management, it is necessary to define variables for data sharing for a transport company and a description of the main information flows. Conceptual models of the main information flows are proposed. The variables in the described information flows are not final and depending on specific features of each mining company, changes in the regulatory requirements and in the activity can be made or new ones can be added.

Based on the participants in the communication channels, the presence of a centralized management organization, the required level of security and data transfer speed, the consensus mechanism Practical Byzantine Fault Tolerant was chosen. It ensures continuous operation, even in the presence of a software problem and the ability to add new participants.

A platform for regulating the contractual data sharing policy has been chosen. Hyperledger Fabric was chosen because it is the closest to the considered organizational structure which needs multi-channel data sharing. The suggested solution provides a fast transaction finality time – e.g. in Hyperledger Fabric it varies from 150 – 200 ms to 2 sec. Exposition of new attack vectors, thanks to increased attack surface. This platform is suitable not only for the transport sector in a mining company, but also for the transport sector as a whole. In addition, Hyperledger Fabric is suitable for other information flows in the mining industry - tracking of resources, electricity, etc.

New perspectives for further research are the classification of the data passed to the DLT system and maintenance of the DLT system.. The attributes of the block are not determined for the defined information flows of the transport company for an outsourcing company, this will be among the future tasks of the team.

This research was supported by the Bulgarian projects under contract: "Study of the possibilities for application of DLT using blockchain in data sharing in mining activities and electricity production from biogas “MEMF-164”.

Abstract. The research is aimed at solving the topical problem of enhancing efficiency of iron ore magnetic separation by applying ultrasonic technologies to identify optimal technological parameters of magnetic separation, improving controlled structural parameters of a magnetic separator and pretreating slurry by high-energy ultrasound to clean the ore material surface from fine-dispersed particles of minerals and slime, as well as disintegrate ore aggregates fed to the magnetic separator. The main tasks involve identifying regularities of influence of slurry pretreatment by high-energy ultrasound on properties of iron ore magnetic separation, determining regulations of improving technological and controlled structural parameters of the magnetic separator using ultrasonic methods, developing and substantiating methods to enhance efficiency of iron ore magnetic separation by applying ultrasonic technologies.

1 Introduction

Sustainable industrial development calls for solving the topical problem of reducing costs and energy-intensity of iron ore mining and processing [1-5]. Energy intensity of Ukraine's mining and metallurgical complex greatly exceeds that of advanced industrial countries [2, 3}. Power consumption of iron ore concentration processes and equipment substantially depends on properties of ore subjected to processing [6-8]. Nowadays, about 5-8 mineral and technological types of ore are processed simultaneously at Kryvyi Rih mining and concentration plants [2, 7]. It is worth noting that each mineral and technological type of iron ore demands such grinding rate to maintain certain granulometric composition in compliance with the size of useful component inclusions, thus ensuring the best ore-grain release and enhancing efficiency of subsequent sorting and separation [9, 10].

Application of ultrasonic technologies to nondestructive control is one of promising methods to enhance efficiency of iron ore concentration, this involving attainment of operative data on technological processes and treatment of ore particles by controlled high-energy ultrasound, in particular, by forming cavitation processes in iron ore slurry [11-13].

The research is aimed at solving the topical problem of enhancing efficiency of iron ore magnetic separation by applying ultrasonic technologies to identifying optimal technological parameters of magnetic separation, improving controlled structural parameters of a magnetic separator and pretreating slurry by high-energy ultrasound to clean the ore material surface from fine-dispersed particles of minerals and slime, as well as disintegrating ore aggregates fed to the magnetic separator. The main tasks involve identifying regularities of influence of slurry pretreatment by high-energy ultrasound on properties of iron ore magnetic separation, determining regulations of improving technological and controlled structural parameters of the magnetic separator using ultrasonic methods, developing and substantiating methods to enhance efficiency of iron ore magnetic separation by applying ultrasonic technologies.

[14-15] suggest applying the ultrasonic method to controlling suspension velocity and accumulating magnetic material inside the wet magnetic separator of low-intensity. To do this, [14] uses the acoustic system of back-scattering and the ultrasonic method to profile flow velocity. Simultaneously, intensity of the back-scattering signal is used to obtain data on local concentration of solids in the flow and accumulation of magnetic materials.

[16] deals with dynamics of slurry magnetic particles in the magnetic separator of low-intensity. The research suggests modelling dynamics of magnetic particles by tracing individual trajectories by means of the COMSOL Multiphysics software package. The research results reveal various distribution of the block of constant magnets and percentage of coupled particles affecting efficiency of separation. [17] considers the simulation model of the dry rotary drum magnetic separator with distribution of probable trajectories of particles leaving the magnetic separator drum. *Empiric relationships* are used to combine particles' trajectories after their discharge from the drum by its rotation and magnetic field.

* Corresponding author: morkunv@gmail.com

[18] is aimed at investigating into the influence of ore particles accumulated in the magnetic separator on separation processes. There are presented research results on profiles of accumulation of particles and their parameters. It is ascertained that pulsating suspension affects the areas of paramagnetic seizure of particles. *At the same time*, increased magnetic induction within a certain range can also increase particle accumulation to a great extent. [19] deals with researches into ore material separation in various types of magnetic separators. It indicates that a complex system of interrelated factors and structural parameters of magnetic separators greatly impacts efficiency of the latter. The research is aimed at studying the influence of external factors on efficiency criteria of magnetic separation. *Meanwhile*, the researches of the mentioned scholars neglect technologies of pretreating solid particles of ore slurry, in particular the ultrasound-based ones.

[20] suggests a magnetic separator model that considers mineralogical data of ore flows when treating *three ore types* depending on their content of the useful component. There are suggested efficiency indices of magnetic separation ranked by their significance that also take into account the mentioned ore classification. The research testifies to the impact of ore mineralogical characteristics on indices of magnetic separation.

[21, 22] investigate into ore material properties affecting separation in the magnetic separator. However, the above researches consider only a limited range of properties, this not allowing reliable recognition of mineralogical and technological types of ore materials.

[23, 24] describe the experiment results of separating ore materials of various mineralogical properties during magnetic separation. There are determined optimal mode parameters of separation depending on certain mineralogical characteristics to increase Fe content in concentrates. However, the mentioned researches do not focus on nondestructive control of solid slurry properties aimed at improving efficiency of magnetic separation.

Thus, analysis of foreign and national researches on the issues under study reveals a great number of scientific works dealing with methods of enhancing efficiency of technological parameters of ore concentration, improving controlled structural parameters of technological aggregates. On the other hand, it is worth indicating that little attention is paid to the issues of slurry pretreatment by high-energy ultrasound to clean the ore material surface from fine-dispersed mineral particles and slime and disintegration of ore aggregates fed to the magnetic separator. Considering this, integrated application of mentioned methods and means requires development of a relevant mathematical apparatus and engineering designs. It is necessary to conduct researches, improve available mathematical models of technological processes and elaborate a set of ultrasonic methods of operative control over iron ore properties and its pretreatment.

2 Materials and methods

The research aims to improve efficiency of iron ore magnetic separation by integrated application of ultrasonic technologies to enhancing technological and structural parameters of the magnetic separator as well as cleaning the ore material surface and disintegrating ore aggregates.

The research idea implies improved efficiency of iron ore magnetic separation due to identifying technological parameters of the process under study (efficiency, solids concentration, granulometric composition, useful component release), optimal controlled structural parameters of the magnetic separator (the angle of the magnetic unit, the rotation speed, distances between the overflow and the separation drum) and slurry pretreatment by high-energy ultrasound to clean the ore material surface from fine-dispersed particles of minerals and slime and disintegration of ore aggregates fed to the magnetic separator.

The working hypothesis involves integrated application of ultrasonic technologies to investigating into regularities of iron ore magnetic separation that will enable substantiating complex methods of improving efficiency of iron ore magnetic separation, enhancing controlled structural parameters of the magnetic separator and pretreatment of slurry by high-energy ultrasound to clean the ore material surface from fine-dispersed particles of minerals and slime and disintegration of ore aggregates fed to the magnetic separator.

Specific features of the research structure and components imply the fact that achievement of the project aim provides for complex investigations comprising identification of regularities of impacts of pretreating slurry by high-energy ultrasound on characteristics of iron ore magnetic separation; determination of regularities of improving technological and controlled structural parameters of the magnetic separator using ultrasonic methods; development and substantiation of methods to enhance efficiency of iron ore magnetic separation by applying ultrasonic technologies.

Thus, it is required to combine research results in the following directions: theoretical and practical research into iron ore magnetic separation; methods and means of operative control over physical-mechanical and chemical-mineralogical properties of iron ore slurry, as well as methods of improving indices of iron ore magnetic separation.

The mathematical model of dynamic effects of high-energy ultrasound impacting solids in the slurry flow is the key element of the research methods. The given model enables formation of conditions for pretreatment of the ore material surface and disintegration of ore aggregates fed to the magnetic separator. Simultaneously, the model considers dependency of the state of fine-dispersed slime, particles of ore grains of ferromagnetic slurry and flocculated unreleased ore aggregates on parameters of ultrasonic oscillations. The integrated system of methods of measuring ultrasonic dynamics of all technological variables enables improved substantiation of the concept of influence of technological factors on qualitative characteristics of magnetic separation of magnetite quartzite of Kryvyi Rih iron ore basin. The method of identifying processes of separation, delivery and dehydration of materials directly inside the magnetic separator under various operating modes will be

 https://doi.org/10.1051/e3sconf/202128008004

developed on the basis of ultrasonic measurements of changes in concentration, velocity and sizes of ore slurry solids.
The method is noted for application of the first and the second harmonics of volume and surface ultrasonic oscillations propagating in the slurry and along contacting surfaces as measuring parameters of intensity. Also, the research methods include the method of increasing efficiency of iron ore magnetic separation that encapsulates slurry pretreatment by high-energy ultrasound to clean the ore material surface, from fine-dispersed particles of minerals and slime and disintegration of ore aggregates fed to the magnetic separator, determination of optimal technological parameters of magnetic separation (efficiency, concentration of solids, granulometric composition, the release rate of the useful component) and optimal controlled structural parameters of the magnetic separator by using ultrasonic measurements.

3 Results and discussion

To simulate the ultrasonic pressure source which is time-variant, the k-wave software package for MATLAB is used in the two-dimensional heterogeneous medium of propagation [25, 26]. The initial distribution of pressure is determined by adjusting parameters of the source.p0. To identify the pressure time-variant source, there can be established both a source mask (that identifies the model net points belonging to the source), and the input of the time-variant source. The source mask is determined by assigning of the binary matrix of the same sizes as the calculated net where 1 is presented by the net points forming part of the source [27].

When acoustic waves reach the edge of the calculated area, they are absorbed by a specific type of the anisotropic absorbing boundary layer [28, 29]. Effects produced by this layer can be observed when propagating waves approach the edge of the calculated area. By default, this layer occupies a band of 20 net points around the domain edge inside the calculated domain identified by kWaveGrid. To avoid side effects, one should not place the source or the sensor points inside this layer. As an alternative, to obtain a perfectly coordinated layer, it can be established *outside* the calculated domain set by the user.

The absorbing boundary layer possesses four properties each of which can be controlled by additional input parameters [28, 30].

Sizes of the absorbing layer on each domain edge are conditioned by the parameter PMLSize in units of the points. By default, there 20 net points in one- and two-dimensional spaces and 10 net points in the three-dimensional space. If the size is a single value, it is used for all Cartesian coordinates. Optionally, the size for each direction can be established separately by setting the *Size* value [x_size, y_size] in the two-dimensional space and [x_size, y_size, z_size] in the three-dimensional one.

Absorption inside the absorbing layer is set by the parameter *Alpha* in the Napier units on the net points. By default, the parameter equals 2 for all the sizes. If absorption is indicated as a single value, it is used for all Cartesian directions. Besides, absorption for each direction can be established separately by setting the *Alpha* value [x_alpha, y_alpha] in the two-dimensional space and [x_alpha, y_alpha, z_alpha] in the three-dimensional one.

The absorbing layer can be located so that it is inside or outside the calculated net created by the user while changing the value of the logic flag *Inside*. If *Inside* is established as *false*, the net inputs increase on each edge by the size set by *Size*.

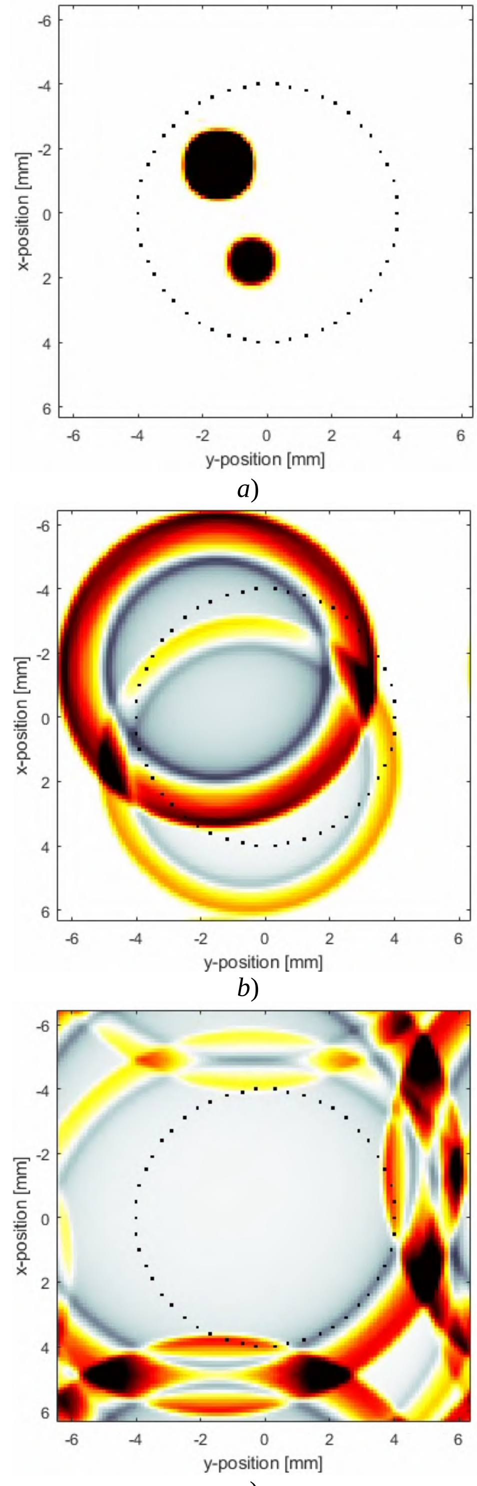

Fig. 1. Dynamics of the acoustic pressure field propagating with the absorbing boundary layer switched off.

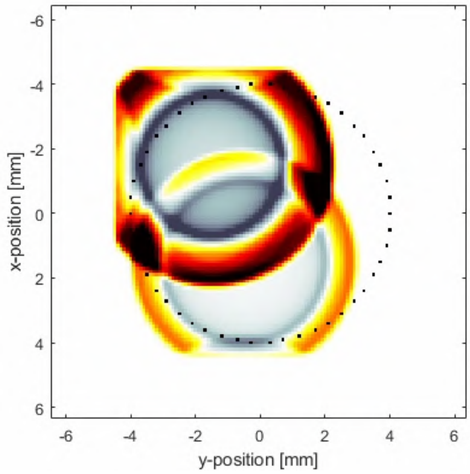
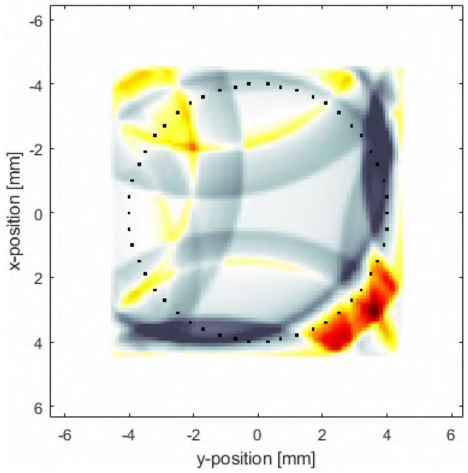
 https://doi.org/10.1051/e3sconf/202128008004

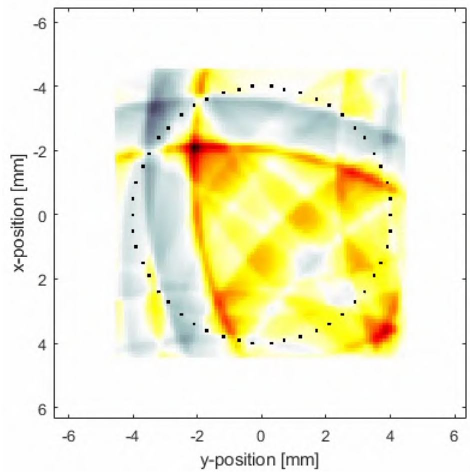
Visibility of the absorbing layer within the simulated space that is reflected during simulation is controlled by the logic input parameter *Plot* (by default set as *true*).



a)



b)

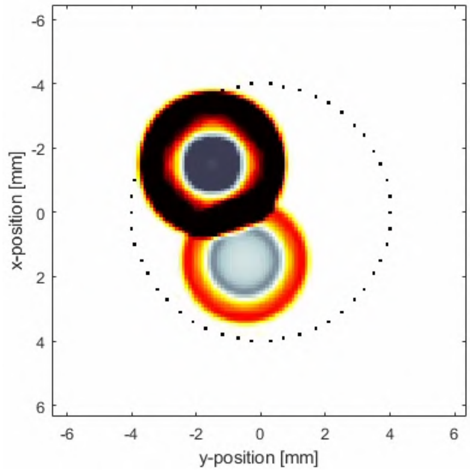


c)

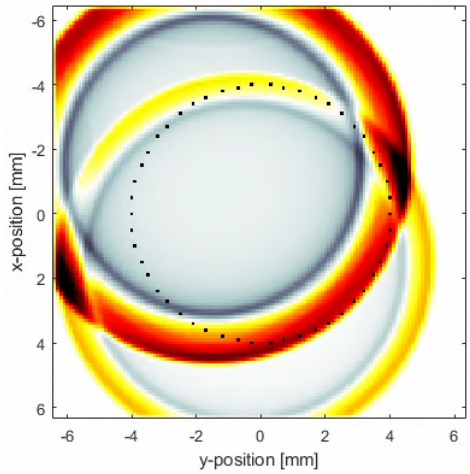
Fig. 2. Dynamics of the acoustic pressure field propagating with the propagation parameter value being too high

To make simulation more accurate, one should make sure the initial pressure distribution and the sensor mask are not within the boundary layer. This can be avoided by setting *Inside* to be *false*. Yet, calculation time will anyway depend on the general size of the net including the boundary layer (i.e. calculations will be the fastest for the nets where the total number of net points in each dimension is given twice).

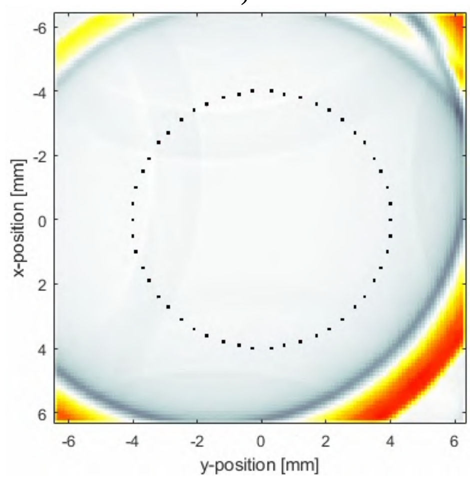
Let us consider some specific cases of adjusting the absorbing boundary layer – without absorption, with too high absorption, the partially effective boundary layer, and the boundary layer set outside the calculated domain.



a)



b)



c)

Fig. 3. Dynamics of the acoustic pressure field propagating with partially effective boundary layer

In software, certain parameters of the absorbing boundary layer are selected by the conventional operator where the variable of choosing the model characteristics is set manually and can take the value from the pre-established totality.

The effect of the absorbing boundary layer can be visualized by switching it off completely. To do this, the parameter *Alpha* is initiated by 0. In such a way, the zero absorption is established inside the layer and the waves leaving one side of the domain reappear on the opposite side. Fig. 1 visualizes dynamics of the acoustic pressure field propagating.

A similar effect is observed if the Alpha value is set too high. It makes the waves reflect from the boundary layer (Fig. 2).

Efficiency of the absorbing boundary layer depends on its size and absorption as well the time step used for modelling: the more time intervals a wave spends in the boundary layer, the more it is absorbed.

An effective absorbing boundary layer can be partially simulated by reducing its size, i.e. setting 2 for the additional input *Size*.

The boundary layer absorbs part of the waves approaching boundaries of the simulation area. Part of reflected waves watched in the previous example can still be perceived by sensors (Fig. 3).

By default, the absorbing boundary layer will be in the net determined by the user, so the source and the sensor should not be determined in this area.

Conclusions

Thus, the working hypothesis of the project implies the integrated application of ultrasonic technologies to investigating into regularities of iron ore magnetic separation that enables substantiation of integrated methods of improving efficiency of iron ore magnetic separation by enhancing technological parameters of magnetic separation, improving controlled structural parameters of the magnetic separator and slurry pretreatment by high-energy ultrasound to clean the ore material surface from fine-dispersed particles of minerals and slime and disintegration of ore agglomerates fed to the magnetic separator.

Annotation. The article is devoted to the development of an effective technology for processing serpentinite ores from the Bozymchak deposit in the Kyrgyz Republic. Based upon the analysis of mineralogical, physical and chemical parameters of the ore, the authors set reasons for the decrease in technological indicators of the existing concentrator and determine concentrating properties of the reviewed serpentinite resistant material by applying methods of intensifying the flotation process by using additional flotation collectors/depressors and introducing the process of mechanochemical activation of the pulp before flotation. In the proposed technological flowsheet, main requirements for the technological flowsheet and reagent suite of processing serpentinite ores are formed and it is acknowledged that an increase in the grinding size, introduction of the selective copper collector and additional depressor determines the prospects for improving the "reagent" component of determining factors of the set task. Materials of the article can be useful for mining and processing enterprises while involving resistant copper bearing, magnesian serpentinite ores in the processing in order to increase the raw material base of the existing mining and processing complex.

1 Introduction

The subject of research is serpentinite ores of the Bozymchak deposit in the Kyrgyz Republic. Serpentinite ores are composed of serpentine minerals (antigorite, chrysotile), carbonates, pyroxene, amphibole, and quartz. The main target copper mineral in this type of ore is chalcopyrite. The grade of secondary and oxidized copper minerals in some samples can reach 50% of the total amount of copper bearing minerals. The grade of serpentine reaches 70-71%. Main components in the ore are copper, gold, silver [1, 2].

According to the geological exploration, main reserves (up to 70%) of the Bozymchak gold and copper deposit are accounted for by serpentinite ores, which, in turn, determines the priority of developing processing technology for this type of raw material.

The ore mineral composition of the deposit is predetermined by the complex tectonic environment of their formation: introduction of granitoid intrusion – contact metamorphism with formation of marbles, corneas, serpentinites and skarns – pre-ore discontinuous tectonics – superposition of hydrothermal processes.

In this regard, two types of ores are developed at the deposit: skarn and serpentinite. Rock-forming minerals of ore skarns are represented by wollastonite, garnet (andradite), pyroxene (augite), quartz, slightly epidote, chlorite, and carbonates. Sulphide minerals are represented by chalcopyrite, bornite, chalcosine, covelline, pyrite.

Serpentinite is a rock consisting mainly of minerals of the serpentine group: lizardite, antigorite, chrysotile, chrysotile-asbestos that have a common chemical formula: $X_{2\text{-}3}Si_2O_5(OH)_4$, where $X = Mg, Fe^{2+}, Fe^{3+}, Ni, Al, Zn, Mn$. Serpentinite is the host rock of many minerals or frames deposits and therefore is a multi-tonnage waste of the mining industry and processing industry [3]. Serpentinite consists mainly of magnesium hydrosilicates, the processing of which makes it possible to obtain magnesium oxide and silicon dioxide.

When processing serpentinite, along with magnesium, concentrates of non-ferrous metals are obtained. Serpentine is leached with hydrochloric acid to obtain chlorinated magnesium solution and silicon dioxide. Chlorine-magnesium solution is purified from impurities by neutralization to obtain an iron-nickel concentrate. Carnallite is synthesized from purified chlorine-magnesium solution [4].

Serpentine-bearing ores can be an unconventional source of magnesium salts, white soot, iron-bearing pigments, and chromite concentrate and chromium compounds. It is proposed to use sulfuric or nitric acid methods for processing of serpentinites. Unlike sulfuric acid, serpentized magnesium and iron-magnesium silicates containing serpentine anthophyllite, talc, quartz, aluminum silicate, clinochlor, and the mineral nontronite, pimelite are leached with the participation of Bacillus bacteria, and nickel sulphides are not leached [5, 6].

The low quality of the copper concentrate is due to the presence of serpentine in it, the mass fraction of which reaches 43%, and presence of intergrowth of iron oxides with chalcopyrite. Losses of copper with dump tailings are associated with its losses with chrysocolla (losses of this mineral with dump tailings are 100%), malachite and azurite (losses of free copper oxides with dump tailings are 90%), and with intergrowth of chalcopyrite with iron oxides [7-9].

For enrichment of serpentinite asbestos ores, friction enrichment, air separation and wet processes are used [10]. To preserve the natural length of high-grade asbestos fibers and maximize their extraction, staged crushing is widely used with the extraction of asbestos fibers as they are released from their connection with the host rocks.

Main difficulties in concentrating of serpentinite ores are associated with the complexity of the ore mineral composition of the waste, among which easy-to-float serpentine minerals predominate.

2 Methods of experiment procedure

The study of the mineral composition of ore and concentrating products was performed using an Axio Imager A1m optical microscope equipped with automated Mineral C7 analyzer and EVO-MA 15 electronic scanning microscope. X-ray phase analysis of ore was performed on ARL PERFORM’X wave x-ray fluorescence spectrometer.

XRD analysis of the initial ore was performed on x-ray diffractometer of powder materials XRD-7000S. Weight parts of valuable components in the initial ore and its processed products were measured using Arcos, inductively coupled plasma emission spectrometer, Solaar, atomic absorption spectrometer, CS-800 sulfur analyzer, Titration Excellence T-70 automatic titration system, and Specord 250 Plus scanning spectrophotometer.

Sample preparation and technological studies were performed using MShL-7 ball mill, ultrafine bead mill, Pulverisette-5 planetary mill, flotation machines FMP-L3, FMP-L1 and FMP-L0.3.

According to the program of works, liberation of ore minerals in serpentinite samples was studied when the samples were grinded to 86.8% – 71μm.

In order to determine preliminarily technological indicators of the processability of serpentinite ore samples, flotation tests were performed according to the existing engineering report and with the use of new collectors. A number of traditional (liquid glass, carboxymethylcellulose) and new generation reagents (modified polysaccharides) were considered as depressors. Considering the work on copper bearing ores with the flotation-active rock-containing component, a series of experiments with the collector/depressor combination using Aero 9863 collector were carried out.

Options with regrinding of the foam product by combined (mechanochemical) activation of the feed before cleaner flotations are considered – as a softened option of grinding to ensure access of reagents to the “fresh” surface. Sulfuric acid was used as a chemical agent. Fig. 1 shows flowsheet of experiments.

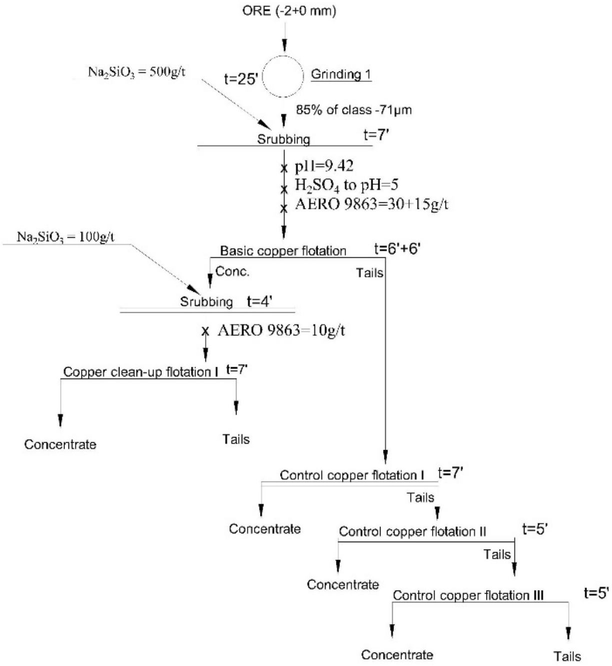

Fig. 1. Flotation flowsheet with mechanochemical activation of flotation feed.

Based upon the results of flowsheet studies, serpentinite ore flotation was carried out in closed cycle (Fig. 2).

Total reagent costs in closed cycle:
* Lime to the recommended pH values;
* Na_2SiO_3 – 1000 g/t;
* Aeroflot butyl – 40 g/t;
* ACC – 100 g/t;
* Aero 9863 – 10 g/t;
* CMC – 150 g/t
* MIBC – 44 g/t

The material composition of on-balance products of serpentinite ore flotation in closed cycle is determined.

3 Experiment results

The results of complex mineralogical analysis, including XRD, optical micro and macroscopic analyses are presented in Table 1.

According to mineralogical analysis, samples consist of magnesium silicates, among which serpentine predominates. Fe oxides and carbonates are present in significant amounts in the sample. The content of sulphide minerals is 10.6% by weight, of which pyrite predominates (8.1% by weight); chalcopyrite accounts for 2.2% by weight. The sample also contains 0.28% of oxidized copper minerals, represented by malachite and chrysocolla in approximately equal amounts.

According to chemical analysis, the main rock-forming elements are MgO and SiO2. Table 2 provides the chemical and phase composition of samples.

There is a noticeable difference in the phase composition of copper (Fig. 2).

According to XRD analysis (Fig. 3), main mineral phases in samples are minerals of the serpentine group $Mg_6[Si_4O_{10}](OH)_8$. Samples also contain significant amounts of pyroxenes (diopside, augite), calcite.

Figure 3 shows intergrowth of sulphide minerals in the initial serpentinite ore.

Microscopically the bulk of serpentinites has the fibrous, thin-scaled structure characteristic of serpentine minerals, sometimes cellular with *Fe* oxides and rare inclusions of sulphide minerals. Serpentine develops along sinuous fractures with formation of the very characteristic cellular structure. The process of serpentinization of olivine is often so intense that it is almost completely replaced by the secondary mineral. Only small relic grains of unchanged olivine are usually preserved in the mass of serpentine. Rare sulphide minerals in serpentinite samples are represented by cobaltine, arsenopyrite, and cobaltpentlandite, which are closely associated with main sulphides, and are found in the chalcopyrite-pyrite fine-grained mass.

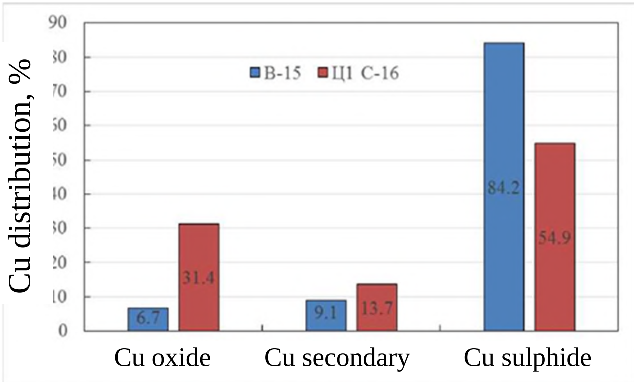

Fig. 2. The phase composition of copper in the original samples of the serpentine type.

According to the studies results on liberation, the liberation of the main sulphide mineral of copper-chalcopyrite in the initial sample is 64.3% rel., when it is grinded to 86.8% - 71 µm. Moreover, the size of free grains of chalcopyrite on 55.1% rel. is concentrated in the size from 10 to 71 µm. The significant share is free grains of chalcopyrite in size less than 10 µm (31.0% rel.). Main intergrowth of chalcopyrite is with non-metallic minerals (24.6% rel.), where the main copper sulphide is represented by 73.3% rel. in size from 10 to 40 µm. The significant part of chalcopyrite is concentrated in polymineral intergrowths (6.1% rel.), where it is mainly in the form of very thin inclusions. Pyrite liberation is 64.2% rel. Free pyrite grains are mainly concentrated in the size from 10 to 71 µm. It is noted that the significant part of free pyrite falls on the size less than 10 µm (32.3% rel.). Pyrite is characterized by intergrowths with iron oxides (17.7% rel.), where they represent the subgraphic structure of intergrowth in each other. Pyrite is 12.5% rel. represented in polymineral intergrowths and 4.9% rel. in intergrowths with non-metallic minerals.

Under flotation according to the existing engineering report, first of all, the change in the visual characteristics of flotation should be noted: process of rougher and scavenger flotation is accompanied by excessive frothing and its resistance, froth color is mainly gray, there is no contribution of copper minerals to the color gamma. The mass pull of the rougher copper concentrate is 20.3% (vs. 3.6% for sulphide ore) with metal grade of 3.69% (vs. 25.5 for sulphide ore). The selectivity of the process is broken due to the flotation-active rock-forming component. In addition, copper losses with dump tailings were 23.19%.

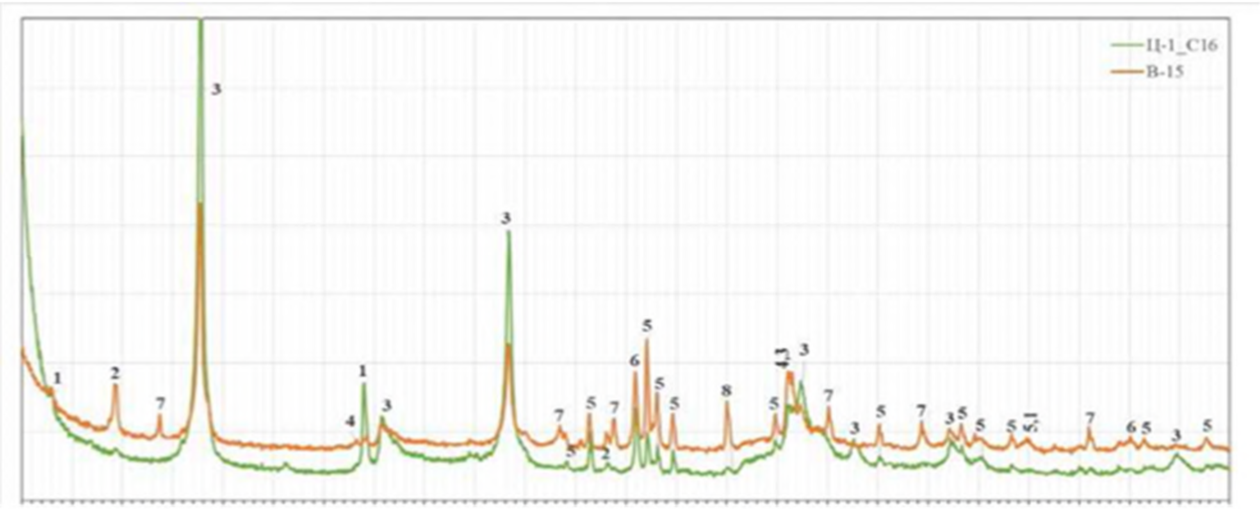

Fig. 4. Diffractograms of serpentinite samples with the designation of main mineral phases: 1 – chlorite, 2 – mica, 3 – serpentine, 4 – magnetite, 5 – pyroxenes (diopside, augite), 6 – calcite, 7 – amphiboles (actinolite), 8 – pyrite.

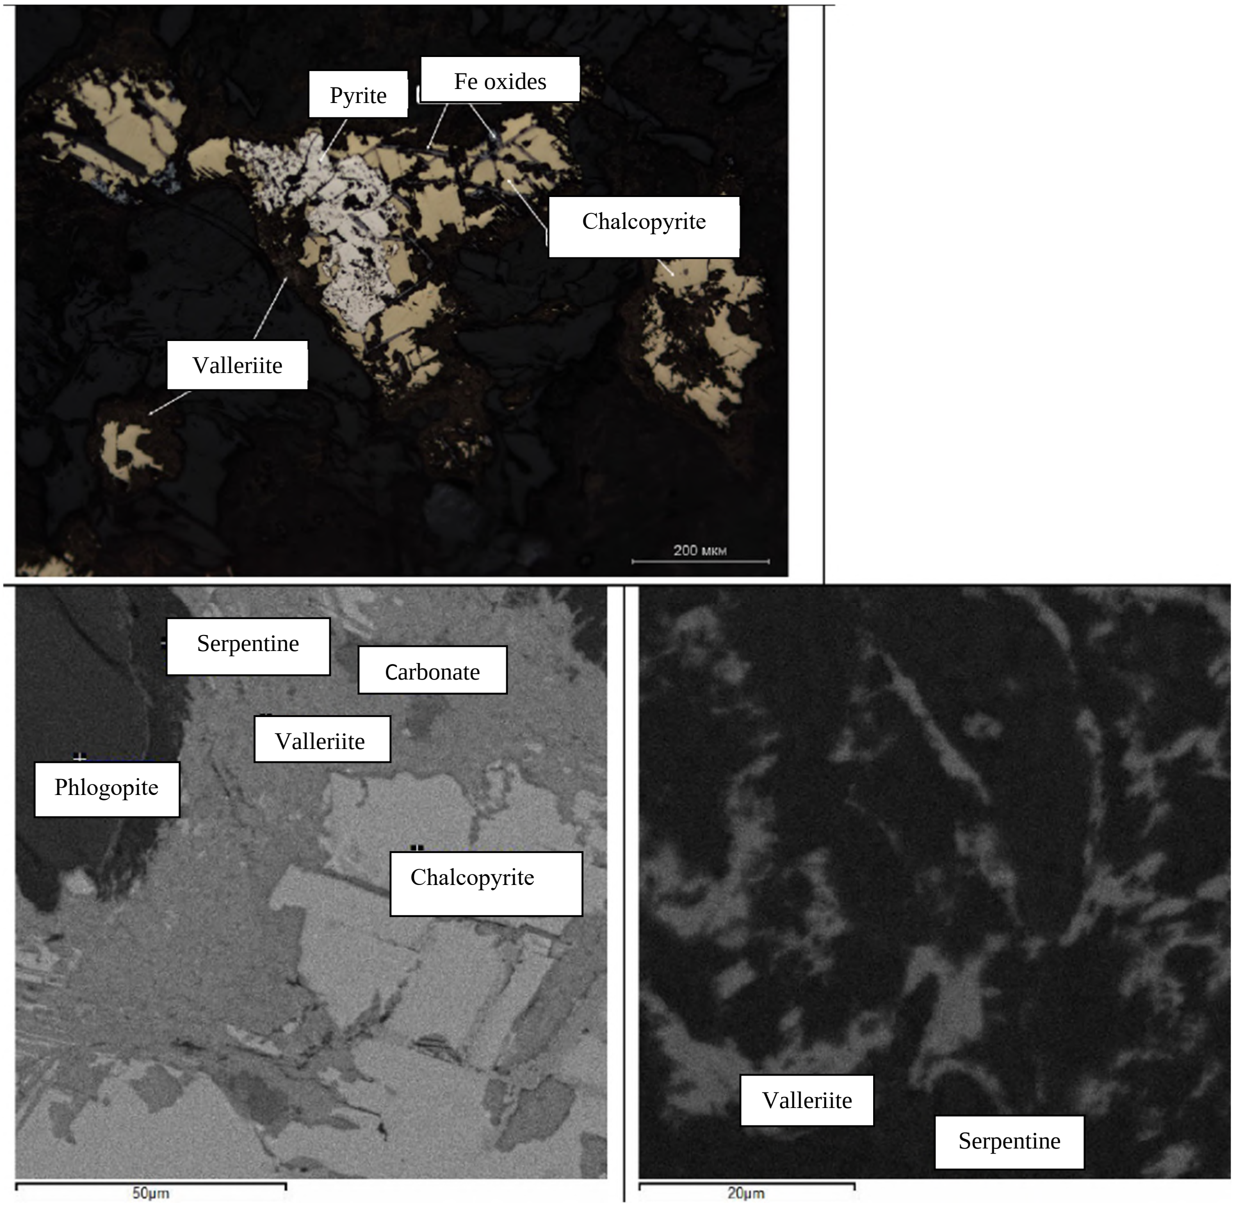

Fig. 4. Characteristic intergrowths of sulphide minerals in the original serpentinite ore.

Mineralogical analysis of flotation products showed that main metal losses are associated with the under-liberation of chalcopyrite and its thin intergrowth.

Table 3 shows the results.

Table 3. The results of flotation on the existing engineering report.

Experience conditions	Product name	Yield	Content, %				Recovery, %			
		%	Си	Fe	SiO2	CaO	Си	Fe	SiO_2	CaO
85% of class - 71µm; PAX - 70 g/t; MIBC - 10g/t; PAX - 25+20 g/t; t = 6 min	Basic copper flotation concentrate	20,3	3,19	15	23,94	4,2	70,4	37,6	14,13	13,16
	Concentrate control copper flotation I	2,2	1,82	19	22,66	4,4	4,36	4,93	1,45	1,49
	Concentrate control copper flotation II	1,34	1,37	16	21,8	3,6	2	2,64	0,85	0,75
	Tails	76,15	0,28	5,9	37,75	7,2	23,2	54,8	83,57	84,6
	Руда	100	0,92	8,3	34,4	6,48	100	100	100	100

A certain effect is achieved when using organic reagents DLM62 and CMC 55C as a depressor, and liquid glass with the constant consumption (200 g/t).

Table 4. The results of flotation using depressors.

Experiment condition	Recovery to total concentrate, %				
	Cu	*Fe*	AlO_3	SiO_2	*MgO*
without depressor	76.81	45.2	17.32	16.43	19.29
liquid glass - 200 g/t	82.64	51.61	13.65	15.54	17.01
CMC 55C - 200 g/t	83.48	52.58	17.27	15.19	18.03
AERO 8860 - 200 g/t	83.22	52.74	19.82	19.19	21.8
DLM 62 - 200 g/t	82.66	50.61	15.08	14.93	16.92
DLM 263 - 200 g/t	82.93	53.1	21.52	17.97	18.29

The main increase in metal recovery (about 6%) is due to redistribution of the share of *FeO* and Al_2O_3, i.e. mainly aluminosilicates are depressed.

Based upon the carried out experiment with the use of Aero 9863 collector, the rougher concentrate is received with copper grade of 5.61% and recovery of 64.94%. With similar consumption of liquid glass at the concentrator combination of amyl xanthogenate and MIBC, rougher concentrate performance is copper grade of 7.18% with metal recovery of 39.67%.

The introduction of (stage) attritioning operations shows "synergistic effect" that contributes to the maximum cleaner of the mineral surface and, as consequence, to the high quality of the received concentrate. This process let reducing losses with dump tailings by almost half (copper loss decreased from 35.50% to 17.37%). The concentrate of the first recleaner achieved copper grade of 15.1% with recovery of 47% at combined mechanical activation with sulfuric acid treatment of the product. At the same time, the combined method of pulp preparation allows to reduce copper losses with dump tailings up to 8.68%.

In closed cycle experiments, the experience of working on high-magnesia talcose ores is taken into account, and approaches tested on ores of this type are implemented in flowsheet solutions. Operations of mechanical activation and regrinding were used as pulp preparation operation. Table 5 shows the results of closed cycle experiments.

Table 5. The results of the locked cycle flotation.

Products	Mass pull %	Grade, %			Recovery, %		
		Cu	*Au*	*Ag*	*Cu*	*Au*	*Ag*
Concentrate	4.32	18.2	17.0	58.00	80.84	82.77	52.20
Tails	95.68	0.195	0.16	2.40	19.16	17.23	47.80
Ore	100.0	0.97	0.89	4.80	100.0	100.0	100.0

The following is noted visually: "dirt" nature of the froth, its increased persistence, and absence of "visible" copper. It is obvious that the froth product is formed by intergrowths with waste rock. As grades of *Fe* and SiO_2 are approximately equal, and *CaO* has decreased by ~10%, the quality of the concentrate mainly suffered due to transition of magnesium-bearing minerals (serpentinite) to the froth product.

The concentrate of the third cleaner consists mainly of copper sulphides (chalcopyrite) by 41.7% and iron (pyrite, marcasite) by 24.7%. The main part of chalcopyrite is in free form, or in intergrowths with pyrite and iron oxides.

Table 6 presents the chemical composition of scavenger flotation tailings received from the initial sample of serpentine ore, and Figure 4 shows the particle size distribution of this product.

Table 6. Chemical composition of flotation tailings.

Element	Grade, %	Element	Grade, %
Cu_{total}	0.195	K_2O	0.4
$Cu_{oxidized}$	0.071	Na_2O	0.038
$Cu_{secondary}$	0.026	TiO_2	0.033
$Cu_{primary}$	0.083	*Zn*	0.015
Fe_{total}	6.04	*Pb*	<0.005
S_{total}	4.0	*As*	<0.001

CaO	7.7	*Ag*, g/t	2.40
MgO	31.2		

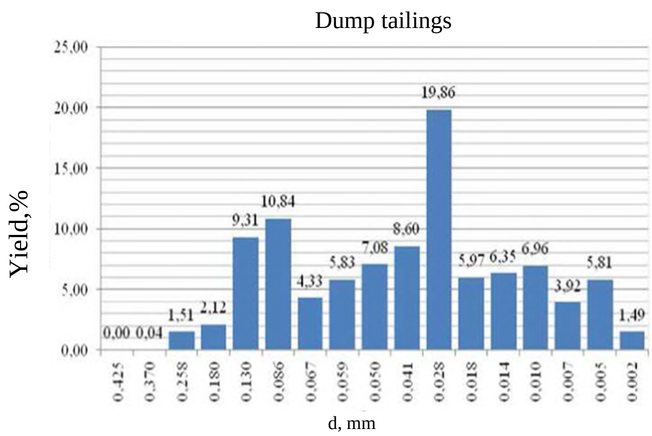

Fig. 4. Particle size distribution of dump tailings in a closed cycle.

4 Conclusions

Main copper losses are associated with chalcopyrite, which is found in intergrowths with non-metallic minerals and polymineral intergrowths together with pyrite and iron oxides. The size of chalcopyrite in such intergrowths is 20-30 µm, with rare exceptions the chalcopyrite grains with the size of about 70 µm are found. Copper losses are associated with presence of complex sulphide hydroxide-valleriite $CuFeS_2(Mg, Fe,Al(OH)_{2-3})$ in tailings, which is in close intergrowth with serpentine and thin chalcopyrite (3-5 µm). The total grade of copper minerals is 0.3%, pyrite and pyrrhotite – 7.3%, iron oxides – 4.0. Non-metallic minerals (88.4%) are represented by serpentine, pyroxenes, and carbonates.

When assessing the recoverability of individual phases of copper, it can be stated that if recovery of sulphide forms of copper into concentrate was practically preserved at the level of sulphide ores, then recovery of oxidized copper was reduced to 24%. This is mainly due to losses of efficiency of the sulfidizer at the stage grinding, which requires special attention to the formation of the sulphidization regime.

Stage grinding allows increasing total recovery of copper on froth products by 10%. However, the issue of obtaining the high-quality concentrate is not solved – the copper grade remains at the same level, while the copper oxide grade is increased to 40%, which confirms the need to introduce the operation of regrinding of rougher concentrate.

Based upon results of traditional approaches [3-9], it is established that increase in the grinding size, introduction of selective copper collector and additional depressor will allow to assess the prospects for improving the “reagent” direction, and main requirements for the technological flowsheet and reagent suite of processing resistant copper bearing, magnesian serpentinite ores are formed:

– stage grinding to fineness of 95% – 74 µm;

– introduction of the depressor for magnesium aluminosilicates;

– introduction of selective collectors for sulphide and oxidized copper;

– finding of the collector for valleriite.

Abstract. One of the main natural gas contained in the coal seams is methane. Most of it is adsorbed on the surface of the coal matrix, another is in free state in different in size and morphology pore spaces or dissolved gas in the waters that associate with the coal seams. The form of presence and the degree of gas saturation depends on the rank of the carbonization process, the petrophysical and physicochemical parameters of the environment. Methane in coal seams is accepted to be categorized as an unconventional energy resource. From this point of view, it is of interest in the Dobrudzha coal basin, located in the North-eastern part of Bulgaria. The specific geological conditions of the basin, the limited study, the presence of a thick covering aquifer make it difficult to extract coal by traditional methods. This requires the use of non-popular for the country methods for energy extraction and establishing relation between the basic parameters of coal seams and their gas saturation. The existing geological-geophysical, drilling and laboratory information is combined in a detailed petrophysical model, which extends over the best presented and studied coal seam (m5) from the field. The basic parameters that reflect the amount of adsorbed gas and are the subject of study are the content of moisture, carbon, ash and the degree of carbonization, expressed by the vitrinite and its reflectance.

1 Introduction

Coal bed methane (CBM) is an integral part of the coal formation process. It is one of the main unconventional resources which became very important for the energy supply in last 20 years. CBM has attracted major attentions worldwide because it is considered as a potential clean source of energy in sustainable future [1]. Coalbed methane is different from conventional natural gas, mainly due to the predominant form of presence adsorbed on the matrix. A relatively small part of it is in a free, concentrated space of different size and morphology or gas dissolved in coal waters. The ratio between the forms of presence of the gas mixture largely depends on the amount of coal substance. Methane reaches 60-80% of the total gas content in coal [2-4].

In the catagenic transformation of coal from brown to black, the formed methane is in the range of 30-40 to 120-150 m^3/t, and in the transition from black to anthracite coal it reaches 200 m^3/t [5]. The accumulated large amounts of methane are under significant pressure and as a result of many factors (geological structure of the basin, properties of the reservoir rocks, water in reservoirs, petrographic composition and coal rank) explosions, gas emissions, its expulsion into tectonic fractures or in adjacent porous rocks are possible. The adsorption capacity depends on the degree of carbonization. It improves upwards - from shiny, brown to black gas and semi-anthracite to super-anthracite [6]. At greater depths, however, the sorption capacity decreases, even with increasing pressure to values above 10 MPa. Coal seams have considerably different characteristics from normal gas reservoirs, especially in gas storage and permeability features. Most gas storage in coal is by sorption into the coal structure, while the permeability is mainly produced by cleat (fracture) or joint controlled. It is also evident that there is a wide variation in coalbed permeability during production phases due to stress effect, which increases with fluid pressure reduction and shrinkage of coal. Coal seams have been described by two main porosity systems including: cleats (uniformly distributed network of natural fractures) and matrix blocks. The cleat (fracture) system of coal seams is divided into the face cleat and the butt cleat [7]. The most important property of coal beds is the permeability, which is mainly created by natural fractures. Coal formation may shrink on desorption of gas and may expand again on resorption. During the primary production phase of methane, two main phenomena are identified to associate depletion of reservoir pressure causing reduction of coal permeability. These two phenomena include: (1) reservoir compaction, which causes an increase in the effective horizontal stress while the reservoir is confined laterally; and (2) gas (mainly methane) desorption from the coal matrix; it causes coal matrix to shrink, reduce horizontal stress, and increase cleat permeability. Economical coal bed methane production depends on four important coal-seam characteristics including gas pressure, gas content, coal-

* Corresponding author: nk.hristov@gmail.com

 https://doi.org/10.1051/e3sconf/202128008006

seam thickness and permeability [8]. The knowledge of coal seams properties and behaviour are the key for successful production process and for increasing the produced volumes of natural gas.

2 Geological settings

Dobrudzha coal field is located in NE Bulgaria, within the eastern slope of the North Bulgarian High, which underwent three structural transformations, manifested with different intensity: through the Carboniferous - of weakly manifested placative and well-defined fault tectonics; in Perm - with a bright manifestation of block tectonics and in the Jurassic and Neogene - with weakly manifested block tectonics (fig 1). It covers area of approximately 200 sq.km. with significant proven coal reserves of about 2 billion tons [9]. Coals are with Carboniferous Age and the commercial reserves has been estimated in Upper Carboniferous Series. The field is non-mineable because of the existence of 900 m thick aquifer above. The field is covered by wells grid with dimensions of 500x500 m with average depth of well – 2000 m. There is conducted 2D seismic survey in volume of 600 km, but the presence of thick highly cavernous aquifer made the results poor and useless in intervals with Carboniferous Age. This is the main reason to investigate wellbore and log data during the drilling process.

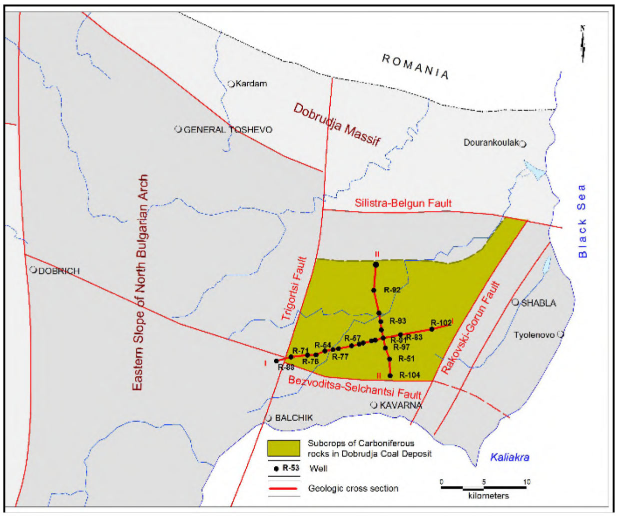

Fig. 1. Dobrudzha coal field location and location of some wells, used for the study.

The field is characterized with complicated geological settings, caused by several tectonic events with Triassic, Cretaceous and Eocene Ages. The major tectonic event, forming the nowadays view of the field is this one with Triassic Age. There are two type of faults in the field – buried one, related to Carboniferous Age and covered by Lower Triassic sediments and younger one, and faults affecting whole sedimental section. The filed is divided by fault to 28 separated areas (blocks) with different coal seam properties. All of the faults have been located using drilling data, because of the poor seismic quality in the area. Fault geometry and influence radius has been investigated using drilling and logging data. Every wellbore in the field have standard for its time logging data such are Calliper, Deviation surveys, Electrical methods (shallow and deep lateral log), Neutron gamma ray, Gamma ray and Density log. With consideration of made lithological and stratigraphical division and correlation of the formation of Upper Carboniferous, the division made before is being confirmed later [10], which is with clearly separation of four main coal formation arranged geochronological as follows: Mogilishte, Macedonka, Krupen and Gurkovo (fig. 2).

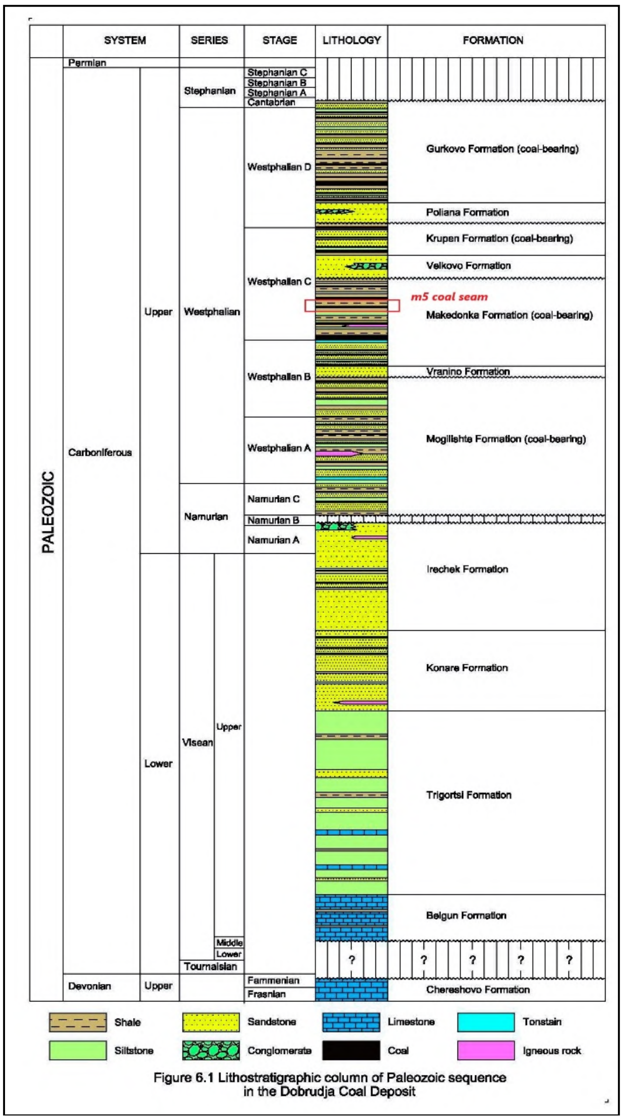

Fig. 2. Litho-stratigraphy of the Carboniferous System of Dobrogea coal field.

The Upper Carboniferous field contain a total of over 86 coal seams, of which 16 are of industrial importance. Coal is black from all classes to anthracite in most of the formations. The rocks containing them are relatively uniform in lithological composition with predominant terrigenous (sandstones, siltstones, argillites, in some places gravelites) lithotypes - products of lake-swamp sedimentation. The total thickness of the coal field exceeds 1300 m. This new updated lithostratigraphic correlation, formations boundaries identification and updated correlation of coal seams from the Upper

https://doi.org/10.1051/e3sconf/202128008006

Carboniferous section [10] is establish by using modern software products and available above-mentioned log records for most of the wells. For identification of coal seams data from core, log records and laboratory analysis of samples in the field are used.

3 Materials and methods

Finding the actual gas content in coal seams can be done directly – in the laboratory, or indirectly. The direct method of determining sorption isotherms involves drilling and cutting core that is immediately placed in canisters, followed by measurements of the volume of gas evolved from the coal over time.

The basic coal seam properties, which are chosen to investigate their relation to the gas saturation are as follows:

– ***Moisture*** - Moisture is an important property of coal and its presence and quantity are directly related to the processes of carbonization and subsequent transformation of sediments. Groundwater and other extraneous moisture are known as adventitious moisture and is readily evaporated. Moisture held within the coal itself is known as inherent moisture and is analysed quantitatively. Adventitious moisture is removed in the laboratory by evaporation in air. Moisture may occur in four possible forms within coal: *surface moisture*: water held on the surface of coal particles or macerals; *hydroscopic moisture*: water held by capillary action within the micro-fractures of the coal; *decomposition moisture*: water held within the coal's decomposed organic compounds; *mineral moisture*: water which comprises part of the crystal structure of hydrous silicates such as clays. Moisture content in a coal decreases the sorption capacity. Because coal loses moisture at a variable rate subsequent to removal from the borehole, a standard moisture content is used when measuring sorption isotherms.

– ***Fixed carbon content*** of the coal is the carbon found in the material which is left after volatile materials are driven off. This differs from the ultimate carbon content of the coal because some carbon is lost in hydrocarbons with the volatiles. Fixed carbon is used as an estimate of the coke yield from a sample of coal. Fixed carbon is determined by subtracting the mass of volatiles, determined above, from the original mass of the coal sample.

– ***Ash content*** of coal is the non-combustible residue left after coal is burnt. It represents the bulk mineral matter after carbon, oxygen, sulphur and water (including from clays) has been driven off during combustion. Analysis is fairly straightforward, with the coal thoroughly burnt and the ash material expressed as a percentage of the original weight. The lower ash content is indicator for more gas content.

– ***Vitrinite*** is the most common component of coal. It is also abundant in kerogen, derived from the same biogenic precursors as coals, namely land plants and humic peats. Vitrinite forms diagenetically by the thermal alteration of lignin and cellulose in plant cell walls. It is therefore common in sedimentary rocks that are rich in organic matter, such as shales and marls with a terrigenous origin. Conversely, carbonates, evaporites, and well-sorted sandstones have very low vitrinite content. Vitrinite is absent in pre-Silurian rocks because land plants had not yet evolved.

– ***Vitrinite reflectance*** was first studied by coal geologists attempting to determine the thermal maturity, or rank, of coal beds. More recently, it is used to study sedimentary organic matter from kerogen. It is sensitive to temperature ranges that correspond to hydrocarbon generation (60 to 120°C). This means that, with a suitable calibration, vitrinite reflectance can be used as an indicator of maturity in hydrocarbon source rocks. Generally, the onset of oil generation is correlated with a reflectance of 0.5 to 0.6% and the termination of oil generation with reflectance of 0.85 to 1.1%

All of the performed logging data was used for coal seams properties estimations applying modern software and approaches. During the drilling process, all wells were cored for all carboniferous section. There is available multiple laboratory test of the core focused on measurements of coal seam properties such as moisture, ash content, Sulphur content, violates. Some core samples were measured for gas content, but their number is very limited. The poor knowledge of coal seam gas content requires performing multiple investigations on log data and calculations based on the laboratory measurements. A number of petrophysical tests have been performed to establish and prove the results obtained synthetically from the available logging data with these laboratory tests. The information is entered into tables and converted into specialized digital formats, which are loaded into software products for geological modelling and interpretation.

4 Result and discussion

After loading the data and their implementation in the already created geological, tectonic and hydrogeological models [11], maps of the distribution of the various parameters by area within the locality for each layer were made. Several coal seams are suitable for gas extraction – those one with abbreviation ***m5***, ***m6***, ***m9***, ***n1***, ***n4***, ***p3*** located in above mentioned formations. The current investigation is focused on ***m5*** coal seam (Fig. 3.) buried on depth interval 1300 – 1900 m in Makedonka formation.

The minimum depths are in the easternmost parts of the locality, and in most of its area of distribution the depth of occurrence is over 1600 m (Fig.4). The average thickness of coal seam is about 5 m, but in the field, there is places where its thickness reaches 13 m. Coal seam ***m5*** is with one of the largest thickness in the field. In the wells in the western and central parts of the field there is a complex structure of the layer - from 2 to 10 layers. The reason for choosing this coal seam is that it is low interbedded, with a large area distribution and a relatively large thickness and has average gas content from 18 to 28 m^3/t of hard coal [12].

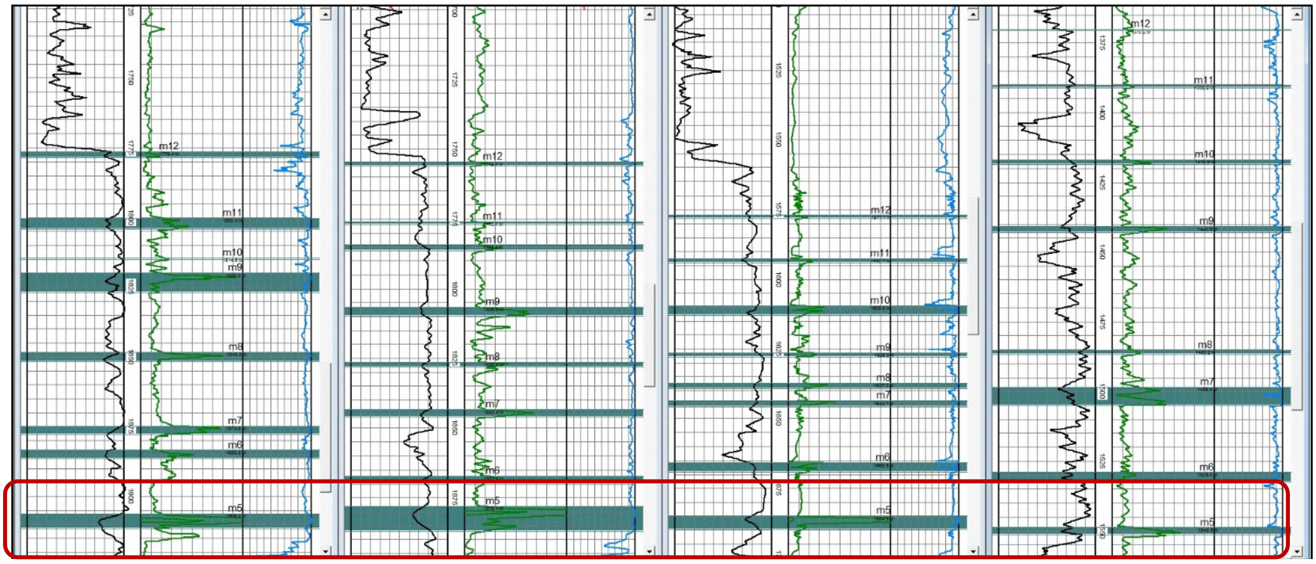

Fig. 3. Correlation scheme of m5 coal seam.

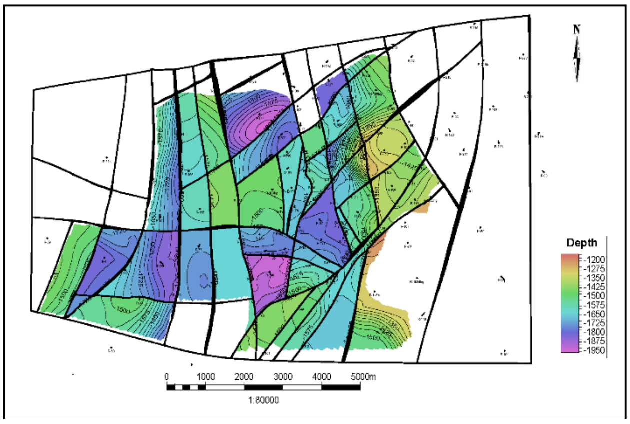

Fig. 4. Depth map of m5 coal seam.

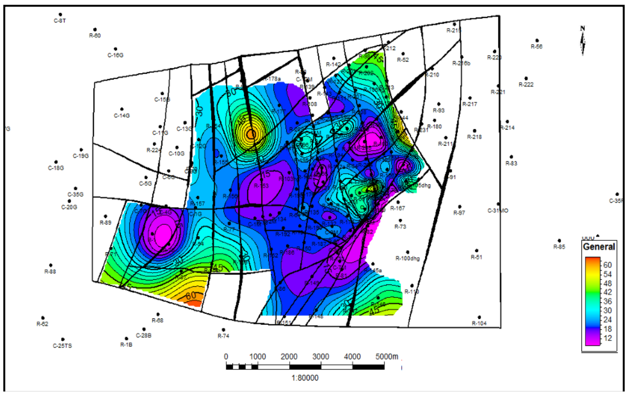

Fig. 5. Ash content (%) map of m5 coal seam.

Using the result of the laboratory tests detailed petrophysical model of the formation which includes ***m5*** coal seam was created. The average ash content is not very high, but its values in different parts of the field vary widely. The ash is unevenly distributed over the area of the layer, as the minimum values are in the central parts of the field. The results are showing higher ash content in coal field edges and low ash content in the middle of the field (Fig. 5). Using data from the investigation it can be conclude that the most suitable part for coal bed methane extraction is the central part of the field. The results from some laboratory test shows 28 m^3/t gas content for this particular area.

The moisture content of the coal varies widely. There is a tendency to decrease the value of this indicator from northwest to southeast. (Fig. 6).

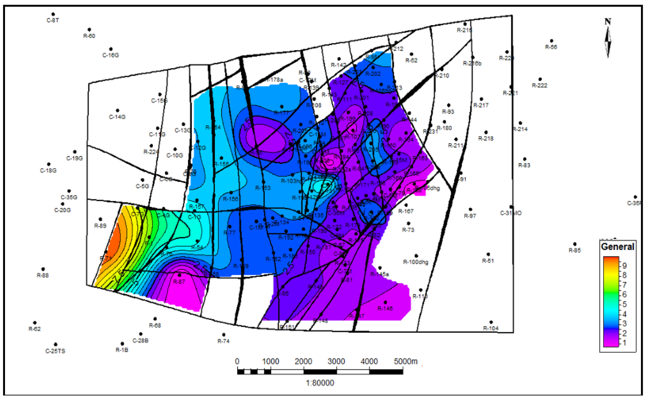

Fig. 6. Moisture content (%) map of m5 coal seam.

The gas content of layer ***m5*** varies in a very wide range, which depends on the depth of formation in different parts of the field. At shallower depths (up to 1600 m) the gas content is the lowest and the composition of the gases is dominated by nitrogen. The layer with the highest gas content is characterized in the range of depth from 1700 to 1800 m, which outlines the so-called methane zone. The composition of the gases is dominated by methane [9]. As the depth of deposition increases, the gas content of the formation decreases, and in the gas phase the amount of methane decreases at the expense of increasing the hydrogen content, especially at depths above 1900 m (Table 1).

Based on the analyses and petrophysical modelling, it can be said that layer ***m5*** is one of the main layers in the Dobrudzha coal field, which are extremely suitable for CBM in almost all key indicators - area and distribution; layer thickness; amount of resources; degree of

carbonization; high yield of volatile substances, moisture; relatively low ash content, petrographic composition dominated by vitrinite macerals, with a significant amount of inertinite; low sulphur content, high gas content and methane content, especially in some parts of the field, low density and relatively high porosity (Table 2).

Table 1. Composition and volume of the gas components distributed in depth in ***m5*** coal seam.

Depth, m	Gas component composition, %							Gas component volume, cm^3

5 Conclusions

Based on the research conducted on the relationship between basic coal seam parameters and gas saturation, it follows that:

– A direct relationship between the studied parameters and the gas saturation of the coal exists;

– A relationship between faults and the distribution of moisture content, ash content and the degree of variation in vitrinite reflectance is observed;

– According to its main indicators, coal seam ***m5*** is suitable for application of CBM technology for methane gas extraction;

– The demonstrated approach finds application for clarification of the interdependence between the studied parameters for the other layers as wells.

Abstract. Object of research - disturbed lands of Ingulets Iron Ore dressing Work (Ingulets GZK) The purpose of work - development and substantiation of technology of realization of principles of cascade waste use. Research methods – field experiment, comparative analysis, systems analysis. As part of the implementation of the cascade waste use principle, the results of research on the impact of the application of sewage sludge on formation of protosoils on the rocks of Ingulets GZK dumps are presented. The application of sewage sludge significantly increases the absorption capacity of overburden. A secondary soil absorbing complex is formed, which is able to accumulate and retain mineral nutrients of plants, especially calcium and magnesium cations. In the conditions of field research the influence of treatment of rocks with organic matter of sewage with introduction of seeds of perspective species was studied. Comparative analysis of vegetation shows a positive effect of the treatment of overburden with organic matter on productivity and morphometric performance of trees and shrubs. A comparison of the average condition of plant objects after treatment with organic matter and control studies shows the following: the vitality of herbaceous and tree species increases; the total projective cover and average height of plants increases; biodiversity.

Introduction

Implementation of the sustainable development strategy involves solving complex environmental problems. The problem of land desertification is becoming increasingly acute around the world and is recognized as global in international instruments ratified by Ukraine: Agenda 21, United Nations Convention to Combat Desertification. Desertification can be both natural and man-made. Desertification is facilitated by the extraction of minerals, which has led to the appearance of disturbed lands in Ukraine on an area of more than 160 thousand hectares. Creation of external dumps, dips and sludge storages contributes to the land degradation.

At the same time, huge amount of waste containing nutrients contributes to environmental pollution, exacerbating environmental problems of climate change. The negative impact of these objects on the environment is manifested in the form of destruction of fertile lands, changes in the hydrogeological regime and other forms. Thus, it is necessary to find non-traditional solutions, the main approaches to which are formed by the theory of sustainable development.

The main idea is the maximum use of natural energies, forces and phenomena. In his report to the Club of Rome, Gunter Pauli proposed that this approach should be considered as the only way of civilization development. It got a figurative name – the "blue economy". Such an economy should be based on technological processes that copy natural physical phenomena, and the waste from one industry should become raw material for another. Thus, the natural cascade principle of waste use in the environment is realized. Unfortunately, there is a shortage of scientific research in this direction.

Traditional notions of land restoration in Ukraine are limited to reclamation, which was widely used in Soviet times. However, because of the need to invest significant funds without real return, often unsatisfactory results of restoration and organizational problems, the traditional reclamation is basically no longer used.

Analysis of its results shows that the main reason for low efficiency is the attempt to create a quasi-natural technosystem based on simplified formal models that are not able to function as primary. The aim of the work is to develop new methods of rehabilitation of lands disturbed by mining operations on the basis of the cascade organic waste use principle.

The development of methods for the formation of secondary ecosystems which meet the requirements of sustainable development on the basis of resource and energy conservation is becoming increasingly important, especially for regions with high human impact. It is known that in energy and resource conservation the leading positions are occupied by the processes of functioning of living systems. In this regard, their involvement in solving technological problems, especially related to the elimination of environmental imbalances, is the most promising area of environmental harmonization.

The main tasks are as follows:

- to review of available methods of organic waste processing,
- to research of content of heavy metals, pathogens in technobiogeocenoses,
- to determine the impact of organic waste on the development of secondary vegetation.

Materials and methods

The research was carried out on the disturbed lands of Kryvbas at the Ingulets GZK. Studies of the structure of the surface and the state of ecosystems were performed using Landsat remote sensing data and ArcView and Google Earth services, which are publicly available.

The following scientific methods were used to solve the set tasks: graphoanalytical; analysis and generalization of statistical and cartographic data; mathematical modeling; system analysis.

Determination of heavy metals content was performed by atomic absorption method, determination of pathogens was performed by direct microscopy, humus content in technosols was determined by the Turin method. The method of squares was used to determine the projective vegetation cover. Its subject is a two-dimensional territorial element. A square with a side of 1 m has been used in geobotany since 1837.

Results and discussion

According to the European Parliament Directive and Council Directive 2008/98/EC (EPOC 2008) on waste, the following waste management hierarchy is proposed: prevention, preparation for re-use, recycling, other recovery, such as energy recovery, recycling. In many countries, the principle of preferential recycling of waste, rather than other ways of disposal, is declared at the legislative level. In Luxembourg, agriculture uses 90% of sewage sludge generated annually, in Switzerland – 70%, in Germany – 38%, in France – 23%, in Belgium – 10%, and the average for European countries and the United States is 32.4% [1]. The use of sludge in agriculture is regulated by Council Directive 86/278/EEC. Sludge should be used taking into account the nutritional needs of plants, and its use should not impair the quality of soil, surface water and ground water. Member states should regulate the use of sludge in such a way as to avoid exceeding the limit values due to the accumulation of heavy metals in the soil. The required rates of sludge application also depend on sludge fertilizer and soil properties. In Germany, liquid sewage sludge can be used in agriculture without dehydration, but the amount of sludge introduced into the soil is strictly controlled to protect groundwater from contamination. In Norway and the Netherlands, sewage sludge is treated by drying and granulating before being applied to the soil as a fertilizer. Prerequisites for the preparation of sewage sludge for disposal as fertilizer are the preliminary disinfection of sludge, as well as the cessation or significant restriction of acceptance by municipal sewage of industrial wastewater containing a significant amount of toxic substances [2]. According to [3], the most common method of sludge processing in the EU-15 in 2014 and 2015 was incineration (47.3% and 61.5% respectively) with subsequent reuse of sludge, including direct agricultural use and composting (48.2%, 38.2%). In Ireland alone, more than 70% of total sludge was disposed of in agriculture, in 7 countries the value ranged from 70% to 20% (over 50% in Bulgaria), in 10 countries less than 20% (0% in the Netherlands, Slovenia and Malta). Malta, the Netherlands and Slovenia belong to the group of countries with the strictest limit values for the main group of heavy metals in sludge. In Italy, disposal methods are distributed as follows: incineration – 20%, burial – 44%, use in agriculture – 36%; in the USA: incineration – 35%, burial – 30%, use in agriculture – 35%; in Poland: incineration – 44%, burial – 33%, use in agriculture – 23%; in Russia: incineration – 20%, burial – 74%, use in agriculture – 6% [4].

The European Union has adopted “End-of-waste criteria for biodegradable waste subjected to biological treatment (compost & digestate): Technical proposals” developed by the Joint Research Center, where sludge was excluded from organic waste allowed for compost production “from waste”.

In Ukraine by the Order No. 342 from 12.12.2018 “On approval of the Procedure for reuse of treated wastewater and sludge subject to compliance with the maximum permissible concentrations of pollutants” the use of sewage sludge is regulated by the DSTU 7369:2013 “Requirements for wastewater and its sludge for irrigation and fertilization”. In accordance with the requirements of current legislation, it is recommended to provide for the use of treated wastewater and decontaminated and dewormed sludge in agriculture (as organic fertilizer) [5]. The design of treatment facilities does not include the final stage of disposal and application of treated sludge. The use of sludge in agriculture is a recommendation, so in Ukraine the most common method of waste management is placing sewage sludge in holding ponds or landfills. Facilities for the disposal of sewage sludge are sources of environmental pollution and require large territories. In this regard, in some European countries, such as Germany, it is prohibited by law to deposit sludge on drying beds [6]. Sludge can be classified as follows: coarse, retained by grates; heavy (sand), caught by sand traps; floating (fatty substances) accumulated in settling tanks; suspensions deposited in primary settling tanks; activated sludge of secondary settling tanks (microorganisms with adsorbed and partially oxidized contaminants removed from wastewater during biochemical treatment); anaerobic sludge fermented in metatanks; stabilized aerobic activated sludge or its mixture with sediment from primary settling tanks in structures such as aeration tanks; activated sludge or sediment in thickeners or concentrators; sludge dehydrated on mechanical devices, dried on sludge beds or thermally dried. The main part of dry residue in the sludge of the primary settling tanks (60–75% on average) and activated sludge (about 70–75%) are organic substances. The organic part of the activated sludge is mainly represented by substances of protein origin (up to 50%) with a fat and carbohydrate content of 30 and 10%, respectively. It contains about half as many proteins and 2.5–3.0 times more carbohydrates than in activated sludge. Possibilities of disposal of waste (changes of some derivative characteristics to receive a product suitable for the further useful application) are determined by its qualitative structure. The composition of sewage sludge largely depends on the composition of wastewater, but most of their components are traditional. Based on the composition, the most common worldwide is the use of sewage sludge as organic fertilizers. Value of such fertilizers in many cases is equivalent to manure and sapropels. The content of plant nutrients in the dry matter of sewage sludge is: 2–7% of N; 1.5–7% of P_2O_5; 0.15–0.35% of K_2O. The content of mummified organic matter improves the soil-forming qualities of disturbed lands. Under the influence of sewage sludge in the soil there is an increase in humus content, improvement of water-physical properties and provision of the main nutrients — nitrogen, phosphorus, potassium, etc [7]. Despite some negative claims, the use of organic sludge as a non-traditional fertilizer to increase soil fertility is one of the possible ways to solve the problem of their placement, as the return of processing waste to agricultural and urban lands is a significant factor in closing the cycle of substances in nature [8]. In Ukraine, out of 6–12% sludge, which is recycled, no more than 1/3 is used in agriculture. In addition to use for growing food plants, sewage sludge and compost from this sludge are used as fertilizers on lands set aside for planting trees and shrubs, creating nurseries, parks, growing perennial grasses for pastures, forage, silage, industrial crops, and also for the restoration of reclaimed lands. Utilization of sewage sludge for the purpose of restoration and cultivation of forests is promising, as the probability of getting heavy metals and pathogenic microorganisms into food chains is minimal [9]. For the forest industry, detailed methods of preparation of a number of organic fertilizers from various components of industrial, communal and agricultural wastes have been developed and recommended for implementation in nursery production [10]. The effectiveness of sewage sludge and the lack of negative impact on grass and woody plants have been proven during field studies in nurseries in the Moscow region [11].

Returning to the qualitative composition of sewage sludge, it should be noted that its disposal in Ukraine is limited by two main factors: sanitary-epidemiological and sanitary-chemical. The epidemiological danger of sludge can be eliminated in many known ways, including such simple ones as drying on sludge drying beds according to DBN V.2.5-75:2013. But agro-ameliorative use of sewage sludge is also associated with the risk of contamination of soil and agricultural plants with chemicals, especially heavy metals, such as Cd, Cu, Ni, Pb, Cr, Zn, Hg, As, Mn, and in some cases Mo, Se, Co, Sr, B, Be, Ba. The content of the above elements in sewage sludge may exceed the background content in natural objects (soil, peat, bottom sediments). It depends on the level of development and profile of industry in the settlement, the technical culture of production, the characteristics of the geochemical province, the presence and area of technogenic landscapes. Sludge from domestic wastewater in cities and other settlements is a fertilizer that contains biogenic elements (nitrogen, phosphorus, potassium, their compounds), as well as micronutrient elements necessary for plant development. The most valuable organic fertilizer, especially rich in nitrogen and phosphorus, is activated sludge. Before use as a fertilizer, the sludge is dehydrated and disinfected. Dehydration is performed by mechanical means (vacuum filters, filter presses, centrifuges) and on sludge drying beds. The following methods are used for disinfection: thermal drying (at 80°C); three-day heat treatment at 55°C; composting at 55°C for 15 days; anaerobic fermentation at 35°C; alkaline treatment for 72 hours at pH 12 and a temperature of 50°C. The most effective disinfection of mechanically dehydrated sludge is achieved by their thermal drying. Drying can be direct (by flue gases, hot air, superheated steam) and indirect (through the heat transfer surface). Direct drying prevails and is carried out in units of various types, for example drum (diameter 1.0–3.5 m; length 4–27 m; direct flow of material and drying agent), fluidized (with mechanical stirring), vibrofluidized and spouted bed, combined. To eliminate the smell of emissions when drying sewage sludge, this operation is often preceded by the application of deodorizing additives. These can be, in particular, ground activated soft lignite coal and/or potassium chloride in the amount of 0.1–0.4 and/or 0.1–0.25 parts per unit mass of dry matter of waste, respectively [12]. To eliminate unpleasant odors, pre-liming of the fermented sludge before dehydration, in particular, by centrifugation, is also used. Additives not only suppress odors, but also destroy pathogenic bacteria by increasing the temperature of the mass to 50–55°C, as well as increase the power of centrifuges by 1.5–2.0 times (N-Niro method). A similar effect is achieved by mixing already dehydrated sludge with lime. The same deodorizing effects are obtained using a mixture of calcium carbide (CaC_2) and lime. Thermally dried sludge does not rot. It is a loose material free from helminths and pathogens with a moisture content of 20–50%, convenient for transportation and application to the soil. However, to avoid dusting, granulation is recommended. In the USSR, "Temporary specifications for thermally dried sludge" were developed. In order to prevent the accumulation of toxicants in the soil and plants, these specifications recommended to apply sludge once every 5 years assuming doses of 10–40 t/ha for sludge with moisture content of 50% or 5–20 t/ha for absolutely dry matter.

Compared to thermal methods, disinfection of sewage sludge in natural conditions on sludge beds is less effective. It requires a lengthy period of time — at least 3.5 years since the last filling. In addition, the distribution of such sediment (with a humidity of 75–80%) on the fertilized areas causes significant difficulties. A new method of disinfection using solar energy is the drying of sludge in greenhouses, which has been used in Germany since 1994. The pre-dehydrated sludge is evenly distributed on the surface of the greenhouse (8–10 m wide) and moved along it by means of an automatic unit of constant agitation and longitudinal movement of the sludge along the front equal to the working width of the greenhouse. The final humidity of the material is close to 10%. On the evaporated moisture specific productivity is 700–800 kg/m2 of the greenhouse at an electric power consumption of 20 kWh/t and prime cost of 100–180 German marks for 1 t.

Along with thermal disinfection and disinfection at sludge drying beds, iodine radiation is used (USA, 1979). The sludge is disinfected in an underground room in stainless steel containers. The source of gamma radiation is cesium-137 (dose of 1 MKu). As a result, all pathogenic microorganisms die, while the nutrients of the sludge are preserved. The total cost of processing 1 ton of dry or combined sludge did not exceed $9.

After dehydration and disinfection, sewage sludge is taken to agricultural fields. Its agronomic application is one of the old and widespread types of disposal. In Germany, when using sludge as fertilizer on arable land, the rate is 5 t/ha per year, and on pastures it is 2.5 t/ha (on a dry matter basis). The experience of joint application of mineral fertilizers with sewage sludge shows a significant increase in the yield of sugar beet, wheat, oats in comparison with the application of only mineral fertilizers. In Australia (Adelaide) sludge from aeration treatment plants is used as fertilizer for gardens and orchards located on sandy soils: application up to 24 t/ha on a dry matter basis increases the yield of vegetables in greenhouses and open ground, improves the structure of soil. Experiments by Polish experts have shown that with the annual introduction of optimal amounts of sludge into the soil, the yield of grass crops increases by 30% and rice by 18%. The predominant use of sludge in urban wastewater as a fertilizer also occurs in other countries (France, Canada, Great Britain, Finland, Japan, etc.).

Sediments can also be processed to obtain soil substitutes. For this purpose, they are placed on sites where reeds and other species of higher aquatic vegetation were planted, and which are equipped with systems for drainage, wastewater separation and its disposal to treatment facilities. The processing depends on the specific conditions and lasts up to 6 years or longer. The obtained material is not inferior in quality to natural soils, has physical and chemical stability and can be used in land reclamation in horticultural farms, etc. [13]. After five years of storage on sludge beds, sewage sludge becomes a soil-like mass with a moisture of 50–60%, which contains 36% organic matter (on a dry matter basis), up to 2.24% of total nitrogen, up to 1.26% of gross phosphorus (P_2O_5), up to 0.3% of potassium (K_2O), a rich set of micronutrient elements. Special requirements apply to the content of heavy metals in sediments in accordance with DSTU 7369:2013 "Requirements for wastewater and its sludge for irrigation and fertilization".

In the USSR, municipal sewage sludge was successfully used in agriculture until the 1990s. For example, the application to the soil of thermally dried sludge of the dry fertilizer shop of the treatment facilities of Orekhovo-Zuyevo in the amount of 30–40 t/ha increased the yield of winter wheat from 3.9 to 33.3 q/ha on raised-bog peat quarry soils. A number of collective farms and state farms in the Moscow region when using sludge as fertilizer increased crop yields by 1.5–2.0 times. There also was an improvement in soil structure. For more than 15 years, the garden and park administration of Moscow has widely used fermented sludge with a moisture content of 80%, removed from the sludge beds: 40–80 t/ha for perennial and annual crops, 100–200 t/ha when laying lawns. Thermally dried lime-containing sludge has become effective means for soil deoxidation. In the areas of development of former peat quarries with the application of thermally dried sludge in doses, which were gradually increased up to 80 t/ha at a humidity of 50%, the reaction of the medium in the soil during the year varied from pH 2.7–3.3 to neutral. Similar results were observed on other less acidic soils at lower doses of sludge. In some southern regions of the USSR, fermented sludge, dried on sludge beds, was used to fertilize vineyards and tea plantations.

In the early 1990s in Russia, the use of urban wastewater as fertilizer in agriculture was prohibited by law. The reason was the increase in the amount of heavy metals and their compounds in sludge.

Studies of substrate properties of overburden dumps have shown the prospects of their use for soil formation. The electrical conductivity of the aqueous extract does not exceed 10 mSm/cm (indicates the absence of salinity), pH values are close to the neutral (6.5–7.0). The absence of phytotoxic properties of rocks is evidenced by the results of biotesting of overburden by germination of radish seeds. The availability of the P and K nutrients promotes self-restoration of biogeocenoses. The development of natural growth processes of communities is inhibited by nitrogen deficiency (N), which underlies the mineral nutrition of plants. The application of organic fertilizers can compensate for the lack of mineral nitrogen and at the same time ensure the stability of its content in the substrate. The source of all forms of mineral nitrogen is the organic matter of sewage sludge. Due to microbiological processes at soil moisture of 25–30% and a temperature exceeding +10°, mineralization of organic matter occurs. Such conditions in the soils of Kryvbas are formed with the beginning of the growing season (early April) and persist for 2–3 months depending on climatic conditions. Sewage sludge has huge reserves of organic matter, the mineralization of which without mixing with rocks less saturated with organic matter can take decades. The main limiting factor in the restoration of biogeocenoses in the steppe zone of Ukraine is soil moisture. Plants experience a lack of moisture for most of the growing season. The formation of secondary biogeocenoses on the dumps of Kryvbas quarries begins with the stages of the "industrial desert". Optimization of humidification conditions is a key task in activating self-healing processes. The study of water-physical constants of the considered substrates shows that rocks of dumps have the lowest volumetric moisture content of withering, which can provide them with the largest range of active moisture. At the same time, the ability of rock dumps to condense moisture from the air significantly exceeds similar abilities of sand, which makes it possible to meet the minimum needs of plants in the dry season. The ability of dump rocks to condense moisture is determined by their mineralogical composition, which is dominated by quartzites. The accumulation of organic matter in the process of self-renewal should promote the aggregation of rocks and the accumulation of moisture. Based on the known equation of water balance, there is an obvious need to ensure the advantage of inflow values over outflow. Excluding from consideration cases of influence of ground waters which on the disturbed lands apeear at depths of more than 5 meters and do not influence development of soil-forming processes, we compare outflow and inflow. Then, based on the fact that in the steppe zone the total amount of precipitation is equal to the sum of evaporation and desuction, by simple transformations we obtain:

$$A = I_{surf} + I_{sub} + I_c - O_{surf} - O_{inf} - O_{sub} \quad (1)$$

where A is the amount of moisture accumulation; I_{surf} is the amount of inflow due to surface runoff; I_{sub} is the amount of inflow due to subsurface runoff; I_c is the amount of inflow due to condensation of moisture; O_{surf} is the amount of outlflow due to surface runoff; O_{inf} is the amount of outflow due to infiltration; O_{sub} is the amount of outflow due to subsurface runoff.

Obviously, the right part of the equation contains values that can be regulated by engineering methods by creating the necessary geological conditions and reclamation structures. Protosoils formed on rocks of degraded lands have porosity indicators significantly lower than natural analogues (light chernozems by 2.8 times, chernozems in eluvium of sandstones and shales by 2.5 times). Due to this, the filtration coefficient is significantly lower in protosoils: 0.2 mm/min. With such water permeability, the formed soils cannot ensure the absorption of all precipitation that falls, and lose some of them with surface runoff. Analysis of particle size distribution according to the classification of N.A. Kachinskiy allows to classify protosoils as strongly granitic. Granitic soils are most common in mountainous areas. They have several features (short profile, gritty consistency), however, which did not prevent them from forming their fertility, the ability to self-restoration, self-regulation. Protosoils of degraded lands, as a rule, develop from coarse clastic soils, which are a mixture of various mechanical elements of stones and boulders (200 m), gravel (40–400 mm), rotted rock (2–4 mm), loam. Humidity of coarse clastic soils is determined by the humidity of the clay aggregate. The accumulation of moisture can help plan the artificial relief of moisture accumulation. On flat areas it is necessary to evenly plan porous accumulative forms in the form of holes, rollers on the edge of the slope, etc. On the slope cracks and furrows along the horizontal relief should be formed. Stimulation of moisture accumulation in the protosoils of degraded lands is one of the promising areas for activating the self-restoration of biogeocenoses. In stony soils, processes of dew formation (absorption of moisture from the air) are created. Limestone rocks, having hygroscopicity, absorb moisture from the air, and then gradually release it into the soil. The movement of atmospheric air brings atmospheric moisture from the seas and water bodies. Changes in atmospheric pressure, the difference in temperature of stones and air led to condensation of water and its accumulation in the soil. Condensation allowed to receive from air in stony soils up to 60 mm of precipitations annually during the growing season. Such moisture reserves allowed the plants to overcome the dry season and maintain their viability in harsh conditions. Application of organic waste (wastewater, sewage sludge, crop biomass, etc.) significantly increases the possibility of protosoil formation on the rocks of dumps, quarries and tailings, organic matter helps to aggregate the soil surface and reduce the rate of water and wind erosion.

In the conditions of field research the influence of treatment of rocks with organic matter of sewage with introduction of seeds of perspective species was studied. It turned out that sewage sludge with an organic matter content of more than 30% can inhibit the development of vegetation, seed germination processes, growth and development of plants [14, 15]. Excess organic matter led to a significant increase in the content of nitrates in soils and their migration in the environment under the action of surface and infiltration runoff.

Analysis of the obtained results and literature data shows that the optimal content of organic matter in soils should not exceed 10–20%. Thus, in order to create optimal conditions for the restoration of disturbed land ecosystems, it is necessary to ensure the mixing of organic waste with weathered (soft) overburden and their application to the surface of the restored soil cover. Traditional means of applying organic fertilizers to the soil cannot be provided due to the lack of tools, the working bodies of which could withstand the processing of stony technical mixtures, which predominate on the lands disturbed by mining operations. The application of sewage sludge contributed to the formation of a kind of mulch on the surface of the soils, which allowed to minimize the loss of moisture through evaporation, contributed to the formation of a lumpy macrostructure. The application of sewage sludge significantly increases the absorption capacity of overburden. A secondary soil absorbing complex is formed, which is able to accumulate and retain mineral nutrients of plants, especially calcium and magnesium cations. The formation of the soil absorption complex significantly improves the water and air regime of soils.

Studies of the chemical composition of overburden have shown a low content of mobile forms of heavy metals.

The content of heavy metals is shown in Tables 1-5.

The content of gross forms of heavy metals in the shales of Ingulets GZK overburden dumps is less than 0.2% for manganese, 0.02% for cadmium, 0.1% for lead, 0.2% for zinc, 0.2% for copper, 0.1% for chromium, 0.2% for nickel of their relative abundance in Earth's crust. The content of gross and mobile forms of heavy metals does not exceed threshold limit values.

The content of gross forms of heavy metals in the clays of Ingulets GZK overburden dumps is less than 0.4% for manganese, 0.02% for cadmium, 0.1% for lead, 0.002% for zinc, 0.2% for copper, 0.0001% for chromium, 0.1%

for nickel of their relative abundance in Earth's crust.

Table 1. Contents of heavy metals in the shales of Ingulets GZK overburden dumps.

The content of gross forms of heavy metals in the limestones of Ingulets GZK overburden dumps is less than 0.2% for manganese, 0.02% for cadmium, 0.1% for lead, 0.1% for zinc, 0.1% for copper, 1% for chromium, 0.1% for nickel of their relative abundance in Earth's crust.

Table 5. Contents of heavy metals in the quartzites of Ingulets GZK overburden dumps.

Form	Contents of heavy metals, hazard class, mg/kg						
	Pb (1)	Cd (1)	Zn (1)	Mn	Cu (2)	Cr (2)	Ni (2)
gross;	15,0	<0,1	8,5	112,0	4,0	<0,1	17,0
mobile: t=25°C	<0,1	<0,1	<0,1	<0,1	<0,1	<0,1	<0,1
t=40ºC	<0,1	<0,1	<0,1	<0,1	<0,1	<0,1	<0,1
water soluble t=25°C	<0,1	<0,1	<0,1	<0,1	<0,1	<0,1	<0,1
t=40°C	<0,1	<0,1	<0,1	<0,1	<0,1	<0,1	<0,1

The content of gross forms of heavy metals in the quartzites of Ingulets GZK overburden dumps is less than 0.1% for manganese, 0.02% for cadmium, 0.1% for lead, 0.1% for zinc, 0.1% for copper, 0.1% for chromium, 0.1% for nickel of their relative abundance in Earth's crust.

In general, for overburden, the content of heavy metals is less than their relative abundance in the Earth's crust and less than the regional values established for Kryvbas. That means that waste can be applied on these rocks without endangering the environment, even if the content of heavy metals in the waste exceeds threshold limit values. According to our research, sewage sludge does not exceed threshold limit values for heavy metals, so its application will not harm secondary ecosystems due to toxic effects, but only bring them closer to the regional relative abundance.

The study of the gross chemical composition of overburden shows that the rocks have enough calcium and manganese, which are plant nutrients, to ensure the fertility potential of secondary soils. Analysis of particle size distribution was performed by screening. According to its results, the technical mixture can be attributed to the coarse clastic soils. Statistical processing of materials indicates the diversity of the particle size distribution of the technical mixture.

Soil formation can be carried out only under the condition of vegetation formation. The development of the latter is constrained by a shortage of diaspore stocks (seeds). The state of the phytocenosis was managed by introducing seeds of tree and shrub species. Pioneer plant colonies had spatial and relief peculiarities. A knotgrass colony with explerent species was formed on flat areas. There were dominated by common knotgrass, or doorweed (*Polygonum aviculare L*). Species that implement the life strategy of explerents have low competitive power, but quickly capture the ecological niches of dump territory. Late annuals predominate among them. In the wet year, yellow sweet clover (*Melilotus officinalle L*) and honey clover (*Melilotus album L*), whose height reached 150 cm, prevailed on flat areas. On the slopes coltsfoot grows, which can occupy up to 5% of the area. Ecological features of the coltsfoot species (*Tussilaga farfara L*) allow to withstand lack of moisture, soil erosion, poor nutrient content of substrates. On the slope there were seedlings of ash-leaved maple, field elm and walnut due to self-restoration processes. In the first year after the implementation of technological actions, seedlings of tree and shrub species were obtained. Formed pioneering communities show a balance between ecological, economic and botanical groups and families. Legumes, represented by several species, have the ability to initiate nitrogen fixation and promote the accumulation of nitrogen of biological origin. The terrace was dominated by an annual plant (common knotgrass), and the stability of such a colony remained low. The slope was dominated by a rhizomatous perennial (coltsfoot) and ash-leaved maple. The development of the root system, the possibility of both seed and vegetative means of plant reproduction determine the prospects for stabilization of emerging ecosystems. The development of vegetation during the application of wastewater has led to the formation of colonies of Chenopodioideae plants on the terrace and on the slope: their biodiversity (52 flora species) and productivity increased. The development of populations of tree and shrub species indicates that the plants have developed and successfully overcome harsh living conditions. Analysis of morphometric parameters shows that the best vitality is still demonstrated by the silver berry (wild olive), apricot and walnut.

Treatment of rocks with organic matter of domestic wastewater has led to a positive dynamics of soils, which is reflected in the enhanced development of vegetation of secondary ecosystems. Comparative analysis of vegetation shows a positive effect of the treatment of overburden with organic matter on productivity and morphometric performance of trees and shrubs.

Morphometric parameters of plants that grow on soils treated with organic matter exceed the control values: by 29% for average height, by 5.9% for mean increment, by 22% for average diameter of the root collar. A comparison of the average condition of plant objects after treatment with organic matter and control studies shows the following: the vitality of herbaceous and tree species increases; the total projective cover and average height of plants increases; biodiversity and total biomass of colonies increases; seed germination is enhanced. The application of organic matter on the surface of the dump allows to provide ecosystems with nutrients, to create a valuable soil structure, to promote the formation of moisture reserves for the scarce summer months.

But the application of sewage sludge promotes the restoration of ecosystems only when they are transferred to a state where the parameters of chemical composition, physical and biological properties are in the optimal range for plants and soils.

When sewage sludge is applited to disturbed lands, they are exposed to natural agents (surface runoff, wind, etc.), which promote the migration of sludge substances in the environment. In order to avoid negative impact on the environment, it is necessary to achieve the safety of sludge during application, or to apply special measures that would exclude the possibility of migration of hazardous substances after application (disinfection, preservation, remediation).

Obviously, the main problem that hinders the use of sewage sludge as organic fertilizers is their contamination with heavy metals. Even with an average content of heavy metals below the threshold limit values, the risk of uneven sedimentation and local pollution, contamination by re-introduction as a result of the accumulative effect, volley pollution of wastewater and sludge, which is not detected by means of control, is not excluded. Under such conditions, the use of sewage sludge as fertilizer on chernozems is associated with the risks of contamination of fertile soils and irreversible changes in their use. Practice shows that the owner prefers to lose the ability to use additional nutrients than to risk losing everything. The urgency of this problem persists with the use of sludge in green construction, when hazardous substances can get into the immediate environment of population of cities and villages.

Sanitary and hygienic problem is one of the key problems. It lies in the content of pathogens (microorganisms, helminths, etc.) in the sludge. Despite various safety measures, it is known that in Japan, a country that has long used municipal waste as fertilizer, infectious diseases, especially ascariasis, are very common. Sludges are very diverse in condition and properties, penetration of substances that carry out disinfection is uneven, the formation of areas in which disinfection does not work is possible. Artificial disinfection methods (infrared and ultraviolet radiation, chlorination, ozonation, etc.) require significant energy consumption and can only be effective for a short period of time. The most effective methods are those that are formed naturally and last for a long period of time. They are achieved by the creation of uniform conditions in which the pathogens die from dehydration, by the formation of an alkaline or acid reaction, and so on.

The problem is the ability to move sludge and substances contained in them. Sewage sludge enters natural ecosystems from the technosphere, has no place in the ecosystem, is not integrated into the natural cycle of matter and energy, and is not a stable element. Sewage sludge, or the substances that make it up, can migrate in space, not appearing where it was applied. Migrations occur under the action of gravity, convection effects, laminar and turbulent flows. Thus, the positive effect of ecosystem restoration can be offset, and in some cases become negative (pollution of surface and groundwater, the spread of infectious diseases).

Organic matter in sewage sludge is in raw form, and at the initial stage of formation is poisonous to most living organisms. To convert to a state suitable for use by soil and plants, it is necessary to carry out the transformation when the raw organic matter is either mineralized or converted into humic and similar substances that are able to form a soil absorbing complex, quickly give nutrients in mobile forms (anions and cations) to the soil solution. The problem of organic matter conversion stems from the need to adapt the artificial element to the needs of the ecosystem.

Wastewater sludge has a concentration of organic matter that is almost non-existent in nature. To include this organic substance in natural cycles, it is necessary to dilute it with inert materials. This dilution when applying organic fertilizers is achieved by scattering on the surface of the field and mixing with the soil in the process of tillage (plowing, cultivation, harrowing). When composting sludge using earthworms, sludge is mixed with waste paper, rags, soil, etc. Dilution of organic matter can be achieved in the process of natural migration under the action of natural agents with surface runoff, wind. The use of natural distribution processes can significantly reduce costs and make recycling processes attractive from an economic point of view.

All these problems of sewage sludge application also occur when it is used to activate ecosystem restoration. In various conditions of disturbed lands, these problems are exacerbated or weakened under the influence of natural factors.

The basic principles of technology should determine the methodological basis of their development, which allows to solve the problems of their application.

Studies of overburden have shown a generally low content of heavy metals compared to modern soils. The content of only some of them exceeds threshold limit values set for soils. This generally coincides with the theoretical generalizations about the biogenic origin of anomalies in the content of heavy metals observed on the earth's surface. According to this hypothesis, plants “pump” heavy metals to the surface, where they are distributed by natural agents (surface runoff and wind). In deep layers of the earth there is no high content of heavy metals, especially in layers that correspond to epochs deprived of the organic world (plants and animals). Based on this, the use of sewage sludge on overburden is environmentally justified. The application of excess heavy metals on the overburden in the general case will help the soils to reach the regional relative abundance.

Thus, for most heavy metals the following is true:

$$C_r = F + B + T \tag{2}$$

$$S < B + T \rightarrow F + S < C_r$$

where C_r is the regional relative abundance of heavy metals in the Earth's crust (regional clarke); F is the content of heavy metals in the soil-forming rock; B is the content of heavy metals of biogenic origin; T is the content of heavy metals of technogenic origin; S is the content of heavy metals in sewage sludge.

If there is a high content of certain heavy metals in the overburden, the genesis of this anomaly has its origins in the special conditions that developed on Earth during their formation in ancient times. This anomaly cannot coincide in time or space with the content of heavy metals in sewage sludge. Therefore, sewage sludge cannot contain the amount of heavy metals that would significantly increase their content in secondary soils.

In natural conditions, pathogens are present in the environment in certain quantities. It is impossible to achieve the complete absence of pathogens. The environment cannot be completely sterile. Sewage sludge after disinfection and pasteurization procedures contains a minimum number of pathogens that does not exceed natural levels. Thus, when overburden that has no biological contamination, almost sterile, comes to the surface of the earth, it is inhabited by either the microflora of sludge or the microflora of the environment. It is obvious that biological pollution from sewage sludge poses the least danger to humans on dumps and tailings in comparison with agricultural, recreational, urban lands, where contact with humans is direct (through the respiratory system, food). Sewage treatment plants are usually located on the terriroty near the industrial site and cannot be completely isolated from the facility employees. Pathogens move with the dust under the action of wind, posing a threat to employees. Dumps, quarries and tailings are located at a considerable distance from the places of concentration of the population (settlements, industrial facilities). They are guarded, which prevents people from accessing them. Therefore, the probability of disease spread when applying sewage sludge to them is the minimum of all possible ways of usage. Contamination of overburden can occur in two ways: by invasion, that is the reproduction of pathogens to the natural level, or contamination, i.e. the application of sludge that already has a natural level of contamination (the presence of invasive pathogens in the environment). Thus the following equation holds:

$$k_p = k_d \times k_0 = k_r \times I \tag{3}$$

where k_p is the value of contamination of overburden and technical mixtures (the number of pathogens per unit volume of sludge — microbes per liter); k_d is the disinfection rate; k_0 is the value of contamination in fresh sludge (number of pathogens of each species per unit volume of fresh sludge — microbes per liter); k_r is the reproduction rate; I is the value of the initial invasion (the number of pathogens at the beginning of the invasion per unit volume — microbes per liter).

The main agents that move sludge and substances are surface runoff and wind. To prevent the movement of sludge, it is necessary to block access of these agents or to minimize their activity. In the first case, a radical solution is achieved; in the second case the solution is partial.

A modified universal equation of water erosion can be used to describe the processes of soil movement under the action of surface runoff:

$$A = R \times L \times S \times C \times P, \tag{4}$$

where A is the loss of the substance; R is the factor of erosion force of precipitation; L is the indicator of slope length; S is the surface slope index; C is the indicator of the surface factor; P is the indicator of technological impact on overburden.

It is obvious that the values of L, S, C, P can be adjusted at the mining stage of dump formation. Access of agents can be blocked by creating an insulating layer between them and the sludge. One can use film, layer of soil, mulch, etc. At present, innovative methods of creating artificial soil, the properties of which can be predicted, are already used. Artificial soils can cover sewage sludge, achieving conservation and isolation.

The conversion of organic matter must be achieved naturally. It takes from 1 to 3 years for raw sludge to ferment under the influence of local microflora. This process can be sped up by the application of active strains of microorganisms, animals that process organic matter in nature (millipedes, worms, etc.).

Dilution of organic matter is very difficult to achieve on stony technical mixtures of disturbed lands. Only surface treatment can be carried out on them. The application of mulch or artificial soil looks much more promising. Artificial soil is formed in the process of mixing weathered overburden with dry ground sewage sludge.

The main methods of application of sludge:

1. Application of small volumes of fermented sewage sludge (0.5 dm^3) into holes during planting of tree and shrub seeds. Such discrete application of organic matter in the norms of 150 mg/dm^2 does not require large amounts of waste (up to 5 m^3/ha). The use of this technique allowed to stimulate the germination of common oak seeds. This technique is difficult to apply on the slope of the dump, where the steepness can reach 45°. Any movement of people and mechanisms on this slope is a threat to occupational safety.

2. Application of a mixture of seeds and fermented sewage sludge on the soil surface in the norms of 100 m^3/ha. After application in the autumn, organic matter has time to penetrate into the soil and to begin its action in the spring to increase nutrient content, soil aggregation and accumulation of moisture. The use of such huge amounts of sludge simultaneously solves the problem of their disposal.

3. Raw sewage sludge with a moisture content of 80% requires surface disinfection with chemicals, such as 10% ammonia solution after loading on a PTS-4 tractor trailer. After transportation to the dump, the sludge is unloaded into the holding pond. After unloading, the surface is disinfected again. Raw sludge with a moisture content of 80% must be kept in holding pond for 3 years to disinfect and ferment the raw organic matter. After holding, the sludge is used by applying in the norms of 100 m^3/ha with a coating by vegetable mulch. Steppe plant sod, rolled lawn, etc. can be used to fix organic matter. Application of sewage sludge from food enterprises to intensify restoration of ecosystems is the most promising area for their disposal.

4. Macroencapsulation is a new way of growing forest zoochories and their crops. Sewage sludge treatment allows the production of multilayer capsules that contain nutrients, micronutrient elements, biologically active substances that stimulate plant development, and biosorbents that allow the transfer of heavy metals to a safe state. Seeds (acorns, drupes) are placed in the capsule and covered with soil.

The effectiveness of such macroencapsulated seeds in agriculture is due to: increased seed germination, accelerated sprout growth and higher plant yields, as well as a significant reduction in the total consumption of organo-mineral fertilizers in field crops, especially on poor soils.

Conclusion

1. Application of sewage sludge significantly increases the absorption capacity of overburden. A secondary soil absorbing complex is formed, which is able to accumulate and retain mineral nutrients of plants, especially calcium and magnesium cations. The formation of the soil absorption complex significantly improves the water, nutrient and air regime of soils.
2. Studies of the chemical composition of overburden have shown a low content of mobile forms of heavy metals.
3. Treatment of rocks with organic matter of domestic wastewater has led to a positive dynamics of soils, which is reflected in the enhanced development of vegetation of secondary ecosystems.
4. In the conditions of field research the influence of treatment of rocks with organic matter of sewage with introduction of seeds of perspective species was studied. Comparative analysis of vegetation shows a positive effect of the treatment of overburden with organic matter on productivity and morphometric performance of trees and shrubs. A comparison of the average condition of plant objects after treatment with organic matter and control studies shows the following: the vitality of herbaceous and tree species increases; the total projective cover and average height of plants increases; biodiversity and total biomass of colonies increases; seed germination is enhanced.

The work was performed under the program "Support of priority areas of scientific research and scientific and technical (experimental) developments of the Department of Earth Sciences of the National Academy of Sciences of Ukraine".

Abstract. The article contains research materials on the storage of man-made deposits, including phosphogypsum dumps. The consequences of long-term operation of phosphogypsum dumps and their negative impact on the environment have been established. The quantitative content of microelements to the soil within the storage of technogenic phosphogypsum deposit was determined. Graphical dependences of phosphorus, manganese, fluorine, mobile sulfur, zinc, nickel content depending on the depth of sampling and distance from phosphogypsum dumps to settlements and the Goryn River are presented. The directions of processing and utilization of the given waste are offered. The elemental composition of phosphogypsum dumps of PJSC "Rivneazot" has been established, in particular, the presence of a group of valuable rare earth elements.

1 Introduction

Mining is the basis of the economy of any country [1, 2]. Since minerals are exhaustible, there is a need to process existing raw materials, including processed products of other industries [3, 4].

The problem of reduction and utilization of waste from various industries is very acute at the present stage of existence of the population around the world [5, 6].

According to the Rivne Geological Exploration Expedition, about 1,200 stationary landfills for soil and groundwater pollution have been identified in the Rivne region. Among the latter, a man-made phosphogypsum deposit poses a significant threat to human life and health, as well as a negative impact on environmental systems. It was formed as an inevitable multi-ton waste as a result of many years of production of phosphoric acid at PJSC "Rivneazot" [7].

Man-made deposit from phosphogypsum dumps of PJSC "Rivneazot", located in Rivne district at a distance of 1.5 km northeast of the village of Metkiv, and at a distance of 1 km east of the village of Rubche (Fig. 1) [8].

There are a significant number of such man-made phosphogypsum deposits in Ukraine and around the world. Most of them are not used, but only constantly accumulated [9].

Significant areas of agricultural land are allocated for phosphogypsum storage [10, 11]. Thus, phosphogypsum dumps of PJSC "Rivneazot" cover an area of 58 hectares and their total volume is 15.2 million tons [7].

It is known that when stored outdoors, under the influence of atmospheric factors, acid residues and large amounts of impurities, phosphogypsum enters groundwater and affects the ecosystem. Among these impurities are found rare earth elements (REE), the extraction of which does not occur [7, 12, 13].

Fig. 1. Man-made phosphogypsum deposit of PJSC "Rivneazot" (photo taken from open sources).

Rare earth elements are widely used in the production of high-tech products. REE includes chemical elements:

* Corresponding author: o.y.vasylchuk@nuwm.edu.ua

Sc, Y, La and 14 elements of the lanthanide family. The total demand for these materials in 2013 amounted to 136 thousand tons [14] and now it is about 200.000 tons, which indicates an increase in demand by 47% [15]. New energy-saving fluorescent lamps, which include: yttrium, lanthanum, cerium, europium, gadolinium, terbium, have become widespread. Due to their low toxicity, REE are used in the manufacture of rechargeable La-Ni-H batteries, which will eventually be able to displace lead-acid batteries in automobiles and nickel-cadmium batteries in computers. Elements of the lanthanide family are used in the glass industry to create optical glass in the charge is injected lanthanum oxide (from 5% to 40%) which increases heat resistance and acid resistance, such glass is used for the production of lenses and prisms of telescopes, cameras, film cameras and laboratory glass [16]. Lanthanum nickel hydride is widely used as the basis for high-capacity batteries for hybrid cars, and the cerium dioxide catalyst is widely used in the petrochemical industry.

Therefore, it is already possible to consider man-made deposits of phosphogypsum as a raw material for the extraction of valuable rare earth elements. According to research, phosphogypsum waste contains up to 1% REE.

The use, processing and utilization of phosphogypsum waste is an urgent scientific and applied problem, the solution of which will improve the ecological situation in the storage areas of man-made phosphogypsum deposits and bring significant economic effect for the national economy [17, 18].

2 Materials and methods

The object of the study is the phosphogypsum dumps of PJSC "Rivneazot" and the adjacent territory (Fig. 2). This is a waste of the fourth class of danger, which is represented mainly by phosphorus oxides that accumulate in the dumps of phosphogypsum [7].

Phosphogypsum refers to calcium sulfate dihydrate. It mainly consists of gypsum ($CaSO_4 \cdot 2H_2O$), impurities P_2O_5 (undecomposed phosphate, unwashed phosphoric acid, crystallized P_2O_5 and water) and other inclusions of trace elements, including REE [19, 20].

Phosphogypsum is a polydisperse material that has a grayish-white color. It is represented by aggregates of particles, lumps with interunit cavities. The density of phosphogypsum is 2.2…2.4 g/cm^3, relative humidity 25…30%, bulk density 0.67… 0.93 g/cm^3, porosity 71.5… 76.3 [21, 22].

Hunting canals have been designed to intercept surface runoff and prevent contamination of soils and groundwater around the perimeter of the facility, and a pumping station has been designed to pump water from the site. Water is diverted to the treatment facilities of PJSC "Rivneazot". Currently, the pumping station is out of order. The water in the canals is highly mineralized, as evidenced by the results of research and dry trees in the riverbed, the water pressure in the canals is 0.5 m. To the object from the side of the village Metkiv there is a concrete road that connects PJSC "Rivneazot" and man-made dumps of phosphogypsum [7].

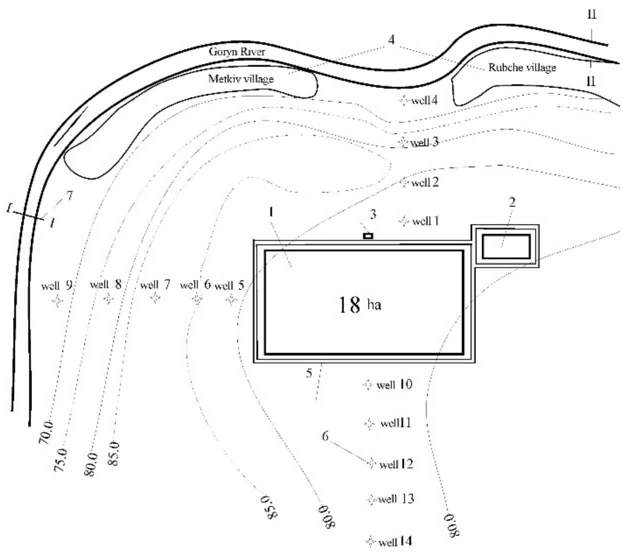

Fig. 2. Experimental area - phosphogypsum dumps of OJSC "Rivneazot": 1 - phosphogypsum dumps; 2 - storage of solid toxic substances; 3 - pumping station; 4 - settlements; 5 - system of channels for interception of surface runoff; 6 - wells for soil sampling; 7 - places of water sampling from the river Goryn, 8 - treatment facilities;w.1 - w.14 - wells for soil sampling; I, II - create for water sampling in the river Goryn.

To determine the content of contamination in soils and in the Goryn River, the study was conducted in two stages: at the first stage, soil and water samples were taken at the Goryn River, and at the second stage, the study results were processed.

To take soil samples, the experimental plot was divided into three sights, which were projected on the lowest points of the terrain. The first line west of the warehouse in the direction of the village. Rubche 1 km long; the second to the south of the object is 1.5 km long; the third to the east of the object towards the forest, 0.9 km long. The total number of wells is 14 pcs.

In Fig. 3 shows a longitudinal section of the target №1.

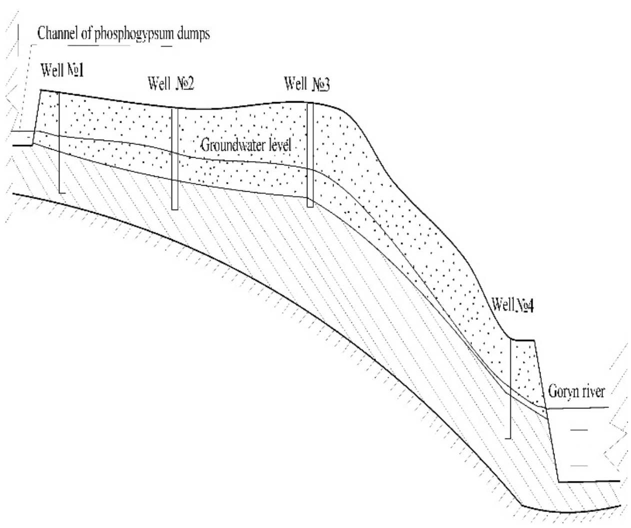

Fig. 3. Scheme of longitudinal section on the target №1: 1 - sand; 2 - loam; 3 - water resistance.

Wells for sampling were drilled by hand drill (geological drill, diameter 50 mm) to a depth of 6 m. Soil

 https://doi.org/10.1051/e3sconf/202128008008

samples were taken every meter, starting from the surface with three repetitions of each sample. The distances between the wells in the first three lines are 50, 250, 300, 400 m, respectively. Along the first line there is a decrease of the territory towards the river Goryn. The distances between the wells in the second line, respectively, 50, 250, 300, 400, 500 m

Processing of data of field measurements was carried out jointly with specialists in the laboratory of the State Department of Ecology and Natural Resources in Rivne region [23, 24].

The raw material for the extraction of rare earth elements was phosphogypsum from the dumps of PJSC "Rivneazot" [7, 8, 25]. Sampling points on the territory of the dump were determined for research (Fig. 4).

Fig. 4. Location of technogenic deposit and place of phosphogypsum sampling on dumps of PJSC "Rivneazot".

Graphical coordinates of the points were determined using a Garmin GPSMAP 64 navigator: sample 1 (50°44'47.9"N 26°10'53.5"E), sample 2 (50°44'45.8"N 26°10'56.4"E), sample 3 (50°44'43.4"N 26°10'60.0"E), sample 4 (50°44'40.8"N 26°11'04.1"E), sample 5 (50°44'38.2"N 26°11'08.2"E), sample 6 (50°44'33.4"N 26°11'15.3"E), sample 7 (50°44'29.6"N 26°11'17.8"E), sample 8 (50°44'29.9"N 26°11'07.9"E), sample 9 (50°44'34.4"N 26°11'01.2"E), sample 10 (50°44'39.0"N 26°10'53.3"E) , sample 11 (50°44'43.1"N 26°10'47.9"E). A total of 11 samples were taken, with a total of 25 kg.

Before the research, a quantitative chemical analysis was performed to determine the elemental composition of raw materials [26, 27].

3 Results and discussion

3.1 Research of phosphogypsum storage landfill

As a result of chemical analysis of water and soil samples taken on the territory of the experimental site, the content of microelements in the experimental samples was determined. The content of nitrates NO_3, fluorine F, mobile phosphorus P_2O_5, mobile sulfur S, zinc, iron, cobalt, nickel, lead, manganese, copper and chromium in soil samples in mg/kg was determined. The pH of the water extract was determined. Graphical dependences of the content of microelements in the soil on the length of the target for each depth of sampling are constructed.

The results are presented for the target №1. It is directed towards the village Rubche and Horyn river, therefore, the obtained data are of the greatest value in terms of impact on soil and groundwater pollution due to the storage of man-made phosphogypsum deposits.

In fig. 5. and fig. 6. graphical dependences of phosphorus and manganese content on the length of the line, respectively, are presented. Samples were taken at a depth of 1 to 6 m.

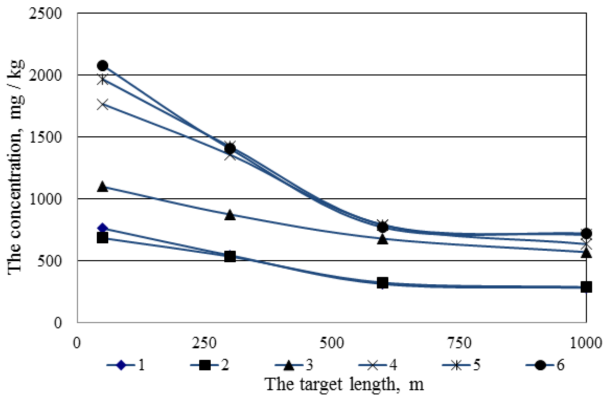

Fig. 5. Dependence of phosphorus content on the length of the target:1 - h =1 m; 2 – h=2 m; 3 – h=3 m; 4 – h=4 m; 5 – h=5 m; 6 – h=6 m.

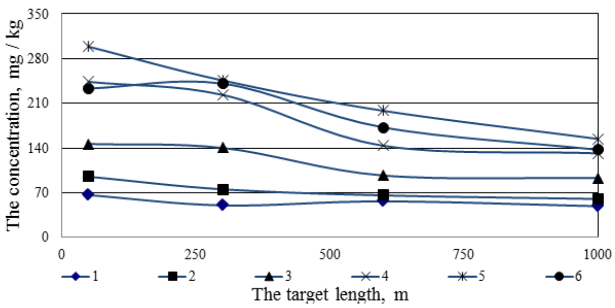

Fig. 6. Dependence of manganese content on the length of the target: 1 - h =1 m; 2 – h=2 m; 3 – h=3 m; 4 – h=4 m; 5 – h=5 m; 6 – h=6 m.

As a result of the analysis of the presented graphic dependences it is established that the concentration of phosphorus varies in the range from 286 to 2078 mg/kg. It is also seen that the concentration of phosphorus in the soil decreases depending on the distance from the phosphogypsum dump, and increases with increasing depth.

 https://doi.org/10.1051/e3sconf/202128008008

The nature of the dependences of the manganese content in the soil is similar to the dependences for phosphorus. Numerical characteristics vary from 48.9 to 298.7 mg/kg.

Studies of the content of microelements from the length of the target at a depth of up to 6 m were also carried out. In Fig. 7 the results are presented at a depth of 3 m, and in Fig. 8 - 5 m.

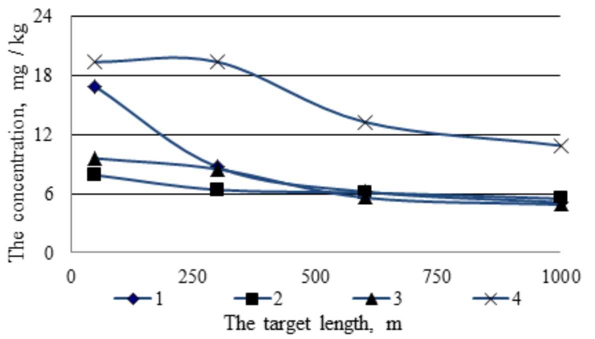

Fig. 7. Dependence of the content of microelements on the length of the target at a depth of 3 m from the soil surface, mg/kg: 1 - fluorine; 2 - mobile sulfur; 3 - zinc; 4 – nickel.

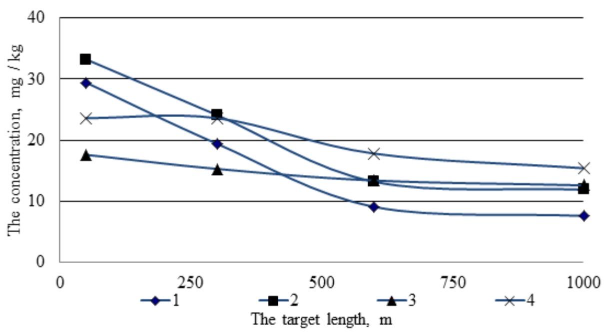

Fig. 8. Dependence of the content of microelements on the length of the target at a depth of 5 m from the soil surface, mg/kg: 1 - fluorine; 2 - mobile sulfur; 3 - zinc; 4 - nickel.

The result of the obtained data showed that the content of such microelements as fluorine, mobile sulfur, zinc and nickel increases with depth, and decreases with distance from the man-made phosphogypsum deposit.

When comparing the data obtained experimentally and the data of the State Department of Ecology and Natural Resources in Rivne region, there is a tendency of significant accumulation in time of harmful chemical elements in the soil. The content of lead, zinc, copper, cadmium, nickel, cobalt, nitrites, manganese, phosphorus exceeds the maximum allowable norms. Thus, in samples taken at a distance of 500 m to the west in 2000, the content of mobile phosphorus in the soil is 332 mg/kg, and in 2019 - 670 mg/kg. As a result, it can be concluded that it is necessary to reconstruct the system of protection of soils and groundwater from pollution by harmful substances on the territory of phosphogypsum dumps near the production site of PJSC "Rivneazot", or the introduction of new more effective methods, which will ensure high-quality interception of pollutants at the outlet of the facility and will not cause an environmentally unfavorable state of the environment. Another way to reduce the negative impact on environmental systems is to develop a project for integrated disposal of phosphogypsum dumps.

3.2 Investigation of man-caused phosphogypsum deposit

From the raw materials obtained for research from phosphogypsum dumps, a quantitative chemical analysis was performed, the results of which are presented in Table 1. For comparison, the results of quantitative chemical analysis of phosphogypsum OJSC "PhosAgro-Cherepovets" (Russia) are presented [28].

Table 1. Quantitative analysis of raw materials from phosphogypsum dumps.

Element	Phosphogypsum of OJSC "PhosAgro-Cherepovets", wt.%	Phosphogypsum PJSC "Rivneazot", wt.%
Sulfates	54.4	52.5
Aluminum oxide	0.2	0.15
Boron oxide	0.0092	0.01
Cadmium	0.00032	0.003
Cobalt	-	0.0012
Chrome	0.002	0.018
Copper	0.0014	0.0018
Iron oxide	0.025	0.034
Potassium oxide	0.055	0.064
Magnesium oxide	0.17	0.187 th most common
Manganese	0.0012	0.013 th most common
Molybdenum	0.00016	0.0056
Sodium oxide	0.27	0.294
Nickel	0.00016	-
Lead	0.00098	-
Strontium oxide	2.04	1.4
Vanadium	-	0.0014
Zinc	0.0018	0.002
Titanium oxide	0.014 ± 0.3	0.016
REE oxides:		
Cerium oxide	0.27	0.26
Oxide dysprosium	0.0042	-
Europe oxide	0.0023	-
Gadolinium oxide	-	0.0015
Lanthanum oxide	0.17	0.205
Neodymium oxide	0.12	0.116
Praseodymium oxide	0.018	0.02
Samaria oxide	-	0.0012
Terbium oxide	0.0014	0.0014
Yttrium oxide	0.016	0.015
REE concentrate	0.6019	0.629

In fig. 9 the content of REE oxides of light group of technogenic phosphogypsum deposit of PJSC "Rivneazot" is presented.

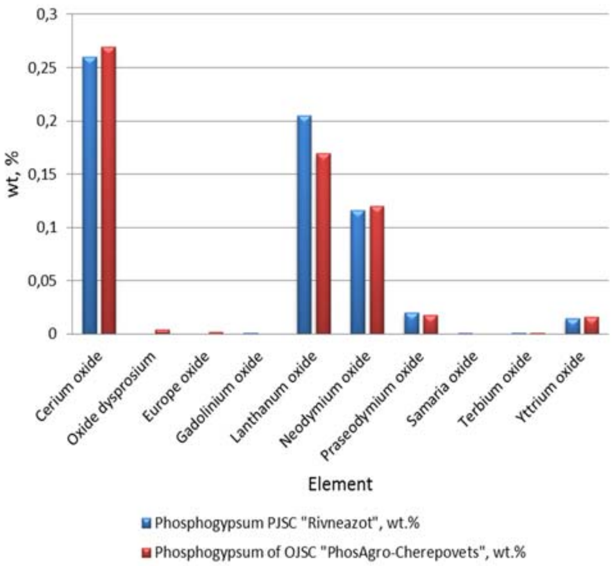

Fig. 9. Oxides of rare earth elements of the light group.

As can be seen from Table 1 and Fig. 9 in the dumps of phosphogypsum PJSC "Rivneazot" presents 8 rare earth elements. The main mass fraction is REE oxides of the light group. These include four elements: lanthanum, cerium, neodymium, praseodymium, the different content of which in concentrates of enrichment determines their commercial value.

3.3 Areas of use of phosphogypsum

The main areas of use of phosphogypsum in the national economy include [29, 30]:

- agriculture, as fertilizers and for reclamation of acid soils;
- use as pavements;
- as creation of X-ray protective designs;
- use as mineralizing additives in the firing of cement clinker;
- in the construction industry, for the production of building materials, production of gypsum binders and production of hydraulic additives;
- as a filler: in the production of paper instead of kaolin, in the paint and varnish industry and in the production of plastics, glass, ammonium nitrate instead of traditional materials (heat-treated phosphogypsum instead of sodium sulfate, etc.);
- mines of coal and other industries - to fill the fastening space and calculation of security strips;
- extraction of rare earth elements.

Conclusions

Solving the problem of processing or utilization of waste that forms man-made deposits of phosphogypsum is an important application, the solution of which will significantly improve the ecological state of the environment.

The research was carried out on the example of a man-made phosphogypsum deposit of PJSC "Rivneazot", located in Rivne region.

According to research, the parameters of micronutrient distribution in the soil around phosphogypsum dumps have been established. The content of lead, zinc, copper, cadmium, nickel, cobalt, nitrites, manganese, phosphorus exceeds the maximum allowable norms. The concentration of these trace elements in the soil decreases with distance from the dumps.

The main areas of use of phosphogypsum in the national economy are agriculture, the manufacture of X-ray protective structures, the extraction of rare earth elements.

According to the results of quantitative chemical analysis, it was found that phosphogypsum dumps contain 0.629% of REE oxides.

Abstract. The purpose of the study is to select an effective methods and equipment for observing deformations in dangerous areas of the terrain, such as areas that are undermined by underground mining. It is known that the topical task of the mine surveying service is to improve remote sensing methods for the state of movement zones with craters, dips, cracks. The research methodology is based on the results of the performed analysis of methods for observing deformations using modern devices and technologies, and experimental work using the developed methodology, which provides for the combined use of digital methods and GPS technologies. Experimental work was carried out at the facilities of the Ordzhonikidze mine using various remote sensing methods, including those developed by the authors. The research used a design consisting of a digital camera and a GPS receiver. The performed analysis of the obtained survey results, using the proposed design of two devices, has shown its effectiveness in remote methods of observing the objects deformations located in areas undermined by mining operations. The scientific novelty of the results obtained lies in the methods development for remote observation of deformations of the ground's surface and objects, based on the structure use from a digital camera and a GPS receiver. This method was developed to increase the efficiency of performing research on objects deformations located in places that are dangerous for finding a person. The efficiency of using terrestrial digital stereo survey when the coordinates of the photographing points are determined with the help of GPS has been proved. The practical significance of the study lies in increasing work efficiency the on monitoring deformations of the earth's surface, buildings and structures located in areas dangerous for field work by traditional methods, which are performed using leveling and measuring the distances between the benchmarks of profile lines, which are usually used on areas undermined by underground mining. The use of terrestrial digital stereo photography with the coordination of photographing stations using GPS allows remote determination of the spatial position of the observed points with the required accuracy. Key words: ground stereoscopic survey, collapse zone, digital camera, GPS.

Introduction

When developing a mineral, a large range of works is envisaged, which also includes the study of the properties of the mineral, the study of the stress-strain state of the field massif and other measures that ensure the most complete and efficient extraction of the mineral with the least losses for the environment [1-8]. However, when mining a mineral, both open and underground, there is a violation of the ecological balance and damage to the environment. As a result of the activities of the mining enterprises, the atmosphere is polluted and the fertile layer is disturbed. As a result, zones with craters, dips and cracks, etc. are formed on the ground's surface. All these negative manifestations are observed by mine surveyors and surveyors in order to take timely measures to reduce their harmful effects on industrial and residential facilities, as well as to protect the environment [9-12].

Therefore, when developing minerals, one cannot do without competent mine surveying. The mine surveying service provides all the work on the extraction of minerals, develops measures for the rational use of subsoil and land, and performs work on the observation of the rocks movement and the ground's surface [13-16].

Ukrainian and foreign scientists are engaged in the development of more efficient systems for the development of minerals and methods of mine surveying support, including measures for their safe production.

An important type of mine surveying, from the entire complex, is mine surveying, the results of which are used to solve many problems. The introduction of modern instruments for their implementation, as well as digital technologies for obtaining and processing data, contributes to the improvement of mine surveying. Many works are devoted to the introduction of photogrammetric methods of shooting using digital cameras and unmanned aerial vehicles (UAV) [17-19]. These methods are effective when observing the state of objects located in areas where it is dangerous for finding a person. Such work is carried out for various similar objects, including for the objects of

* Corresponding author: dlavgeod@gmail.com

mining enterprises, where deformation processes are observed.

When choosing a surveying camera and an aircraft, they are guided by the requirements for the accuracy of solving a particular problem. It is known that the accuracy of a document created from the results of a digital survey carried out with a UAV is influenced by the surveying parameters and the characteristics of the survey equipment. This work is devoted to the study of these questions.

1 The use of software in photogrammetry

The modern photogrammetric methods are characterized by a high level of automation. Most of the operations that were previously performed by highly skilled performers can be performed by ordinary operators [20-22]. In many cases, the operator does not even need special knowledge of photogrammetry, since special programs are used to perform the survey and process the obtained material. Almost all software tools use ready-made processing templates, for example, Pix4D has 3D Maps, 3D Models, Ag Multispectral templates. In turn, templates are divided into those that carry out processing with low requirements for detail and accuracy and those that allow processing with high values of detail and accuracy. Some templates are designed to process data from different thematic cameras Ag Modified Camera or Agrgb, Thermomap Camera, etc. Nowadays such works as orientation of images on special photogrammetric devices (mutual, external orientation), which required a high qualification of the performer, are no longer performed. Even the construction of phototriangulation, the creation of photocircuits is carried out using software products. When designing and performing aerial photography of an area or an object, a minimum of knowledge about longitudinal and transverse overlaps, camera resolution, etc. is required. Calculations for the design of the survey are carried out according to the program using a computer, taking into account all the necessary parameters of the camera and the requirements for the scale and accuracy of the document (plan or orthomosaic), which is created based on the results of the survey. The initial data is set by the operator. However, to perform some work, special knowledge and experience is still required, for example, when drawing up situational and topographic plans for complex objects, which are deep quarries, when it is necessary to correctly position the recognition signs, select shooting parameters, and show elements on the plan with the required accuracy career, not just horizontal lines [23,24].

As a result of the automation and computerization of most processes, some photogrammetric methods have changed significantly or disappeared altogether. First of all, this concerns the methods in which a lot of routine field and office work was used, and some methods have turned from high-precision to survey. In support of this, we can consider phototheodolite photography, which has now changed and uses handheld or tripod photography, and is used to create overview digital models and presentations, or is an addition to aerial photography from unmanned aerial vehicles (UAV). In programs such as Photomodeler or Agisoft Metashape, the operator can build a digital model in a conditional coordinate system from any images (images) that have overlapping. Nowadays, amateur 3D models of architectural monuments, museums and other objects are often used in everyday life, tourism, and other spheres. Nowadays, professional ground surveying is rarely used to solve high-precision tasks. A significant number of programs and software complexes have been developed for the widespread use of unmanned aerial vehicles and digital imaging technologies.

2 The simultaneous surveying research

Phototheodolite photography, in the form in which it was used earlier, was much more accurate than aerial photography. A number of factors contributed to this:

- high binding accuracy of photographing stations and images;
- close-up of the image;
- lack of "blurring" of the image;
- high resolution of photographic plates that were used for photographing;
- the presence of a reference device made it possible to orient the camera relative to the photographing basis.

With the use of modern technologies when performing field work, the first factor that concerns the binding of photographing stations still exists in the form of determining the point coordinates from which the survey is performed, using standard autonomous GPS devices that can be installed on shooting cameras (for example, on Canon EOS 6D camera), or using separate GPS modules that work through the camera's hot shoe, such as the GP-E2 receiver. GPS devices of this class do not have the ability to receive differential corrections.

As a result, the camera positioning accuracy is from 5 to 8 meters in the planned position, and up to 10 meters in height. In many cases, this accuracy is sufficient to create a 3D-scene of an object.

The lack of "blur" in the image is explained by a technological leap in the creation of high-quality digital matrices for cameras, automatically or in manual mode is corrected and corrected by raising the ISO speed. Nowadays, cameras with wide-angle lenses that are mounted on UAV have found widespread use. When using them, in contrast to the narrow-angle (long-focus) ones, the amount of “blur” is insignificant and is not a critical factor. Increasing the ISO speed contributes to the appearance of "noise", but this does not significantly affect the accuracy of measurements on the model, that is, this factor is not critical either.

It is known that phototheodolite photography differed from aerial photography in higher accuracy; this was facilitated by the availability of a reference device. In the implementation of modern digital photography, this factor, which made it possible to obtain a high accuracy of terrestrial phototheodolite photography, replaces the use of a large number of images, the use of reverse photogrammetric intersection and high accuracy of pattern recognition [25-27].

 https://doi.org/10.1051/e3sconf/202128008009

The presence of one control point allows you to replace the process of camera orientation relative to the baseline. Another reason for not using camera orientation is the inappropriateness of software for this type of surveying.

It is known that the initial deformations studies of mining facilities objects, it is necessary to begin with the reconnaissance process of the area. When examining an object, for example, a displacement zones, it is necessary to determine the deformation values, velocities, volumes of extinguished voids, identify areas for special attention, etc [28,29].

On the territory that is located in the zone of displacement from the work of the Ordzhonikidze mine, the previous study was based on the results of aerial photography using the Sensefly drone with the following shooting parameters:

- flight altitude 203 m;
- coverage area 1.87 km²;
- shooting positions 844.

A camera mounted on a drone has the following characteristics:

- focal length f = 18.5 mm;
- pixel size 3.91 x 3.91 microns;
- the number of pixels is 24 million;
- shooting resolution: 3.89 cm/pix.

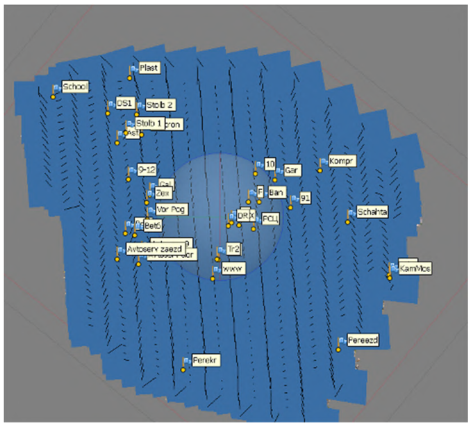
In addition, 975134 tie points, 2582845 projections with a reprojection error were used: 0.391 pix.

When aerial photography of mining facilities objects with significant differences in altitude, such as open pits, multi-tiered dumps, sinkholes zones, recognition signs should be located on them much more often than on a flat territory. Therefore, it is necessary to mark points on areas dangerous for a person, which is undesirable. But when creating a network of identification marks, you can get rid of the need to mark points in dangerous places Today, finding a person in a dangerous place can be replaced by the use of remote sensing and coordination methods. For this, it is advisable to determine the point coordinates from a line of intersection, built from four fixed points, or to determine them using the "reflectorless" mode of electronic devices.

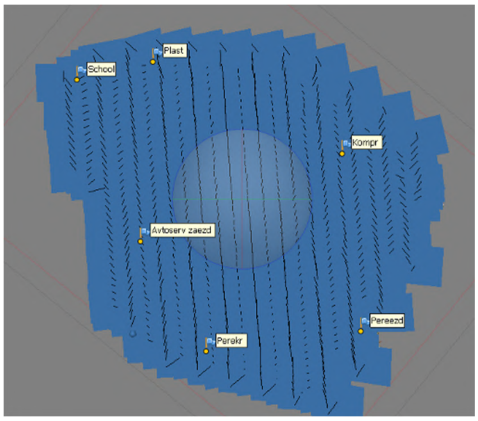
The authors investigated the influence of the location of identification marks on the determining accuracy the spatial coordinates of the studied points. In the first case, all identification marks were included in the processing (Fig. 1*a*), and in the second, only identification marks located along the outer contour of the site (Fig. 1*b*).

The deformation values in the displacement trough, which is formed from the influence of underground mining of the Ordzhonikidze mine, can have values from several centimeters to several tens of meters. Therefore, when exploring this dangerous territory, it can be divided into sections for which definitions can be used with varying accuracy.

If for a funnel with a depth of several tens of meters, in the center, the deformation values can be determined roughly, with an accuracy of 1 m to 1.5 m, and then it is possible not to mark the points directly in the funnel. But if it is necessary to ensure the accuracy of determining the position of the points of 0.1-0.3 meters, then marking is mandatory.



a



b

Fig. 1. Layout of identification marks: *a* - over the entire area; *b* - along the outer contour.

In fig. 2 shows a raster image of the funnel (Fig. 2*a*) and the distribution of errors in the values of deformations over the funnel field (Fig. 2*b*). The distribution of deformation values is shown in different colors, where they are more than 1.3 meters, they are indicated in red.

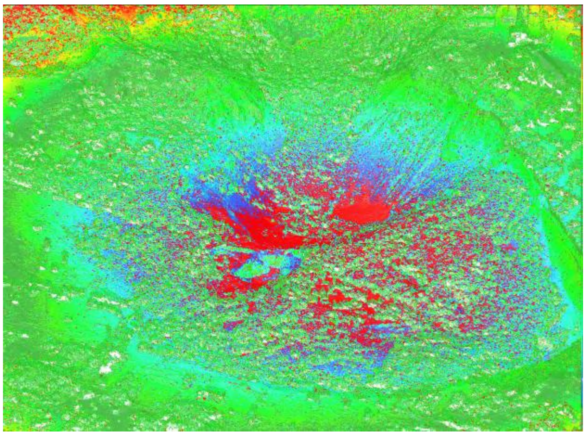
Root mean square errors on identification marks are shown in the graph (Fig. 3). The results of the analysis made it possible to exclude identification marks, the errors of which are more than 0.25 meters, from the use for orienting images.

3 The joint use of a digital camera and a GNSS receiver

The accuracy that aerial photography guarantees is sufficient for general surface monitoring, but for surfaces that have significant elevation differences, it gives large errors. Examples of such surfaces are the quarries sides, dumps and the surfaces of funnel-forming zones. To improve the observations accuracy of deformations, it is advisable to use ground stereotopographic survey.

It is shown in [30,31] that it is expedient to study the areas deformations where the deformations are from 50 to 100 mm and more by the method of ground stereotopographic survey. But the method of ground stereotopographic survey considered earlier by the authors has a number of disadvantages, which consist in the mandatory presence of identification marks and in the need to fulfill the requirements their layout. Also, a significant drawback was the impossibility with the required accuracy to link the images in the areas dangerous for finding a person.

a



b

Fig. 2. Image of the funnel (*a*) and the distribution of deformations (*b*).

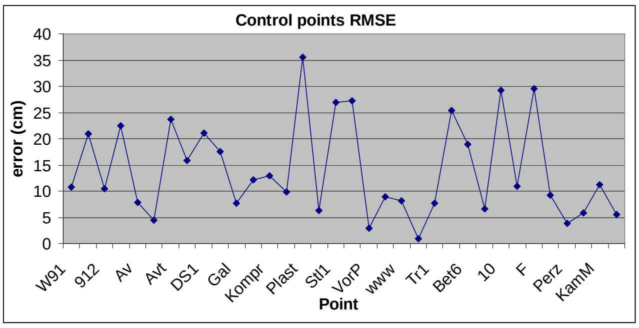


Fig. 3. Errors on identification marks.

When studying the deformations of quarry sides and dumps, as well as other mining enterprises objects, using ground digital survey, it became necessary to increase its accuracy [32]. For this, a design of the device was developed, which allows determining the coordinates of the photographing station with an accuracy of 5 to 15 mm, depending on the observation time, PDOP and distance to the base.

The device is designed on the basis of a Canon EOS 750D digital camera and a Topcon HIPER Plus GNSS receiver (Fig. 4).

Fig. 4. Device design appearance, consisting of a digital camera and a GNSS receiver.

The design has an optical plummet (3), which is attached to a standard three-pin tribrach (1) through an adapter (2). Thanks to this, the adapter can be easily removed and an electronic total station is installed in its place. The GNSS receiver is attached with four pins (4) that allow you to adjust (decrease or increase) the distance to the camera. The hole in the plate (6) has a larger diameter than the bushing (5), which allow the GNSS receiver to be accurately centered over the camera (Fig. 5).

Fig. 5. Elements of the device.

With the help of this device, in May 2020, survey work was carried out from six stations, the distance between which was from 55 to 65 meters. The distance between the first and last photographing stations was 230 meters, and the distance to the base was approximately 200 meters (Fig. 6).

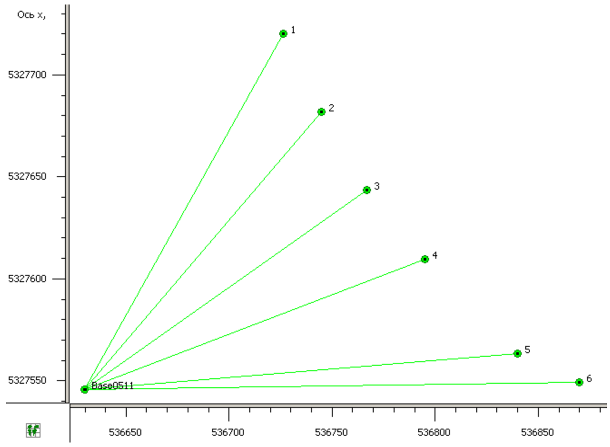

Fig. 6. Location of photographing stations and bases.

The studies were carried out on the territory, which is characterized as a zone of funnel formation from the activities of the Ordzhonikidze mine Central GOK. There are many mined out space in the mine take boundary; therefore the surface and subsoil are in a constant dynamic process. The speed of deformation processes on the day surface depends on the location in the depths of the areas with intensive mining works; therefore, work on predicting its further state is complicated by the fact that the mine is working.

To increase the accuracy of the survey results using device structure appliances, the survey parameters were pre-selected and the elements of the internal orientation of the camera were investigated, the accuracy of which significantly affects the accuracy of determining the position of survey points.

When using modern software for processing photographs (images) with standard settings, the focal length mode "Approximate" is used and the approximate focal length of the camera is taken. After adjustment, this value changes, and for each image its own focal length value is obtained. This also applies to other elements of interior orientation (distortion, main point coordinates). In addition, for each photographing station, coordinates X, Y and Z are determined, which characterize its spatial position. Approximate mode is used for most landmark surveys.

When the position of the photographing point is known with sufficient accuracy, the “Fixed” focal length setting mode is usually used.

In this case, the focal length was determined by photographing the KL-1000 reference ruler and determining the distance to the object using a Sokkia SET630R electronic total station. The defined focal length was 785.521 mm.

Also, in the process of calibrating the camera, the dimensions of the matrix of the Canon EOS750D camera were refined, which amounted to 22.657 mm x 15.104 mm.

The work investigates the research results of the influence of the determination accuracy of the focal length of a professional digital camera on the determination accuracy of the single point positions (Fig. 7) and their mutual position (Fig. 8) according to the digital model obtained from the survey results. In this case, the surveying was carried out without the use of recognition signs.

If, during surveying, the coordinates of the photographing station position are determined with an accuracy of 5 mm, and the focal length is determined with an error of 1 mm, then one can expect an error in determining the position of the studied points in the range from 0.7 m to 0.9 m.

With a rough determination of the coordinates of the photographing station position, for example, with an accuracy of 5 m, and with an error of 1 mm in the value of the focal length, the error in determining the position of the studied points can range from several to tens of meters.

Conclusion

The proposed method for performing ground-based digital surveys, with the coordination of photographing stations, using a GPS receiver installed on them, makes it possible to increase the efficiency of monitoring the objects deformations located in dangerous zones of rock movement and the ground's surface.

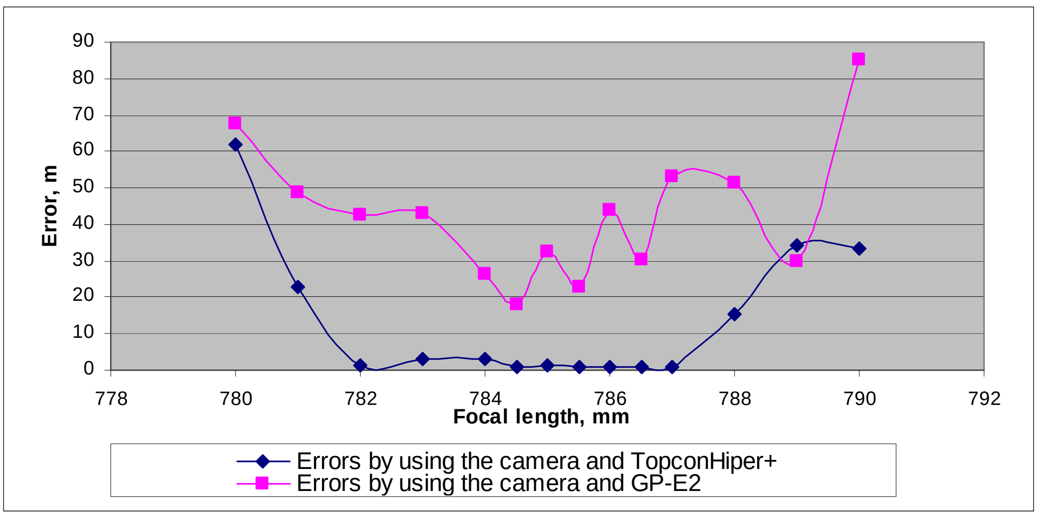

Fig. 7. Dependence of the accuracy of determining the position of points on the accuracy of the focal length.

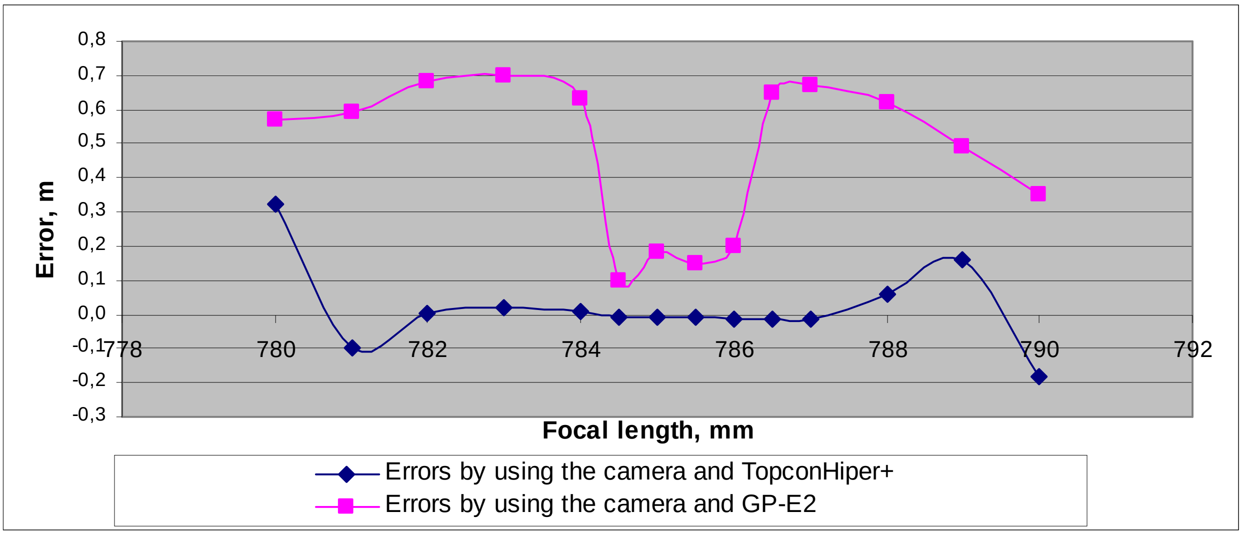

Fig. 8. Dependence of the accuracy of determining the relative position of points on the accuracy of the focal length.

At the same time, the accuracy of determining the coordinates of the studied points, without the use of identification marks, which are necessary for orienting images, increases 10 times or more. It is clear that the proposed technique will also improve the accuracy of work in which identification marks are used to orient the images. But such studies have not yet been carried out by the authors.

The authors are grateful to the administration of the PRIVATE JOINT STOCK COMPANY “CENTRAL IRON ORE ENRICHMENT WORKS” for the opportunity to carry out the research at its objects.

Abstract. The work analyzes current technologies of ore mining applying self-propelled equipment in underground conditions; studies practices of using the equipment in general and for broken ore transportation only; considers performance of mining enterprises in similar mining-geological and mining-technical conditions; analyzes and generalizes causes of high ore loss and dilution rates in underground mining in Kryvyi Rih iron ore basin, thus revealing a problem of providing high efficiency and increased ore extraction with minimal quality deterioration. Marketable ore production is affected by decreased quality and high broken ore losses. Incomplete balance ore extraction when breaking and drawing ore from the stope results in deterioration of mining indices. Ore dilution with waste rocks leads to decreased ore content in the mined mass as compared with that in the ore massif. The research enables development and substantiation of the rational technology of ore drawing and transportation as well as designing a new structure of the loading face to ensure increase of the drawn ore quality indices.

1 Introduction

In Kryvyi Rih iron ore basin, iron ores have been mined for over 150 years [1,2,6,7]. At first, mining operations were performed in open pits and later – in underground mines. First underground mines were only several dozens of meters deep. Main equipment applied was a pickaxe for breaking and horses for ore transportation.
Nowadays, underground mines are more technologically developed, efficient and secure. Complete mechanization of stoping, namely principal and auxiliary processes, has become the main trend of their development [6,37-39].

At present, a high level of stoping mechanization is demonstrated by foreign mines which are more technologically developed than national ones due to the fact that complex implementation of self-propelled equipment as well as mechanization of technological processes started there in the middle of the 20th century. Implementation of self-propelled equipment and mechanization had a comprehensive character [6,7,40,41].

In Ukraine, introduction of self-propelled equipment was not large-scale. In the Soviet Union, this type of equipment was mainly introduced at uranium deposits and, to some extent, at the ZZRK underground mines [7,42-44].

In Kryvyi Rih, self-propelled equipment was used on a trial basis in 1980s-1990s. Its implementation at Kryvbas underground mines was a forced decision caused by the fact that obsolete machines were not able to provide high-technology mining. This necessitated implementation of advanced underground mines' practices [1,2,45,46].

2 Methods

The research aims to study and enhance basic stoping processes, develop technological measures to increase efficiency of mining ore from stopes applying self-propelled equipment.

To reach the set objective, the following methods are used:

- analysis and study of underground operations with applied self-propelled equipment;
- enhancement of drilling and blasting operations applying self-propelled equipment;
- development of efficient structures of the draw level when applying load-haul- machines;
- enhancement of stoping methods and technologies when applying self-propelled equipment at Kryvbas underground mines.

3 Results and Discussion

In mining ore deposits by underground methods, all the underground mining operations are divided into main and auxiliary ones [1-4].

Main underground operations include: ore breaking, broken ore drawing, transportation and loading, rock pressure control.

* Corresponding author: kalinichenko@knu.edu.ua

At present, one of the most widely applied schemes consists in breaking ore by vertical blasthole rings on the vertical compensation space [4-8]. As a rule, it is used for ores with insufficient stability of horizontal, or even inclined, exposures of compensation rooms [1,47,49,50].

Here, blasthole rings are drilled from drill drifts. Ore is broken by layers with a millisecond delay between the adjacent layers necessary for forming additionnal exposure areas [2,12,48,51].

People, materials and equiment are transported along the block raise.

In ores of medium and over medium hardness and stability where significant exposures may occur, breaking can be performed on the horizontal compensation space, or the horizontal undercut.

At this breaking scheme, vertical blasthole rings are drilled from drill orts. To clearly contour the stope, drill orts are driven on the block boundaries. Ore is broken on the horizontal undercut. Primarily, blastholes of the lower layer are broken, then blastholes of the overlying level with a millisecond delay and so on bottom up [1,13,52,53].

In case of insufficiently stable iron ores with no horizontal exposures and with the vertical compensation space being impossible due to technical reasons (e.g. insufficient dip angle and ore body thickness), there are applied schemes of breaking with vertical blasthole rings on the inclined compensation space [6,7,9,10].

The suggested scheme of drilling the block is applied in similar conditions. Its application is mainly aimed at decreasing impact of detonation products on workings of the draw level. In addition, the inclined exposure of the compensation room is more stable than the horizontal one when forming the horizontal undercut. The inclined compensation space is formed for the full width of the stope (panel). Then from the drill ort (drift), vertical blasthole rings are drilled and broken on the inclined undercut [43,54-56].

Breaking is performed in sequence starting from the lower row of boreholes. To reduce the impact blow of the broken ore on workings of the receiving level, part of the broken but not drawn ore is left on the draw level to create a kind of cushion that reduces negative impacts of detonation products on workings of the receiving level. With the same purpose, adjacent ore layers are broken with a millisecond delay.

Historically, application of self-propelled load-haul machines started with their introduction at foreign mines in the middle of the XX century [11-14].

When choosing parameters of self-propelled equipment, it is necessary to consider technological tasks first. It is its reliability, not price, that matters.

For Kryvbas, these factors are a problem, too, that requires immediate study and solution. According to the research data [2,13,15,16], the value of a diesel machine is 1.5-fold less than that of an electric one with similar characteristics.

However, comparison of traditional mining technologies and those applying self-propelled equipment speaks in favor of the latter. The authors of [12,17-19] state that with self-propelled equipment the average monthly meterage per syndicate is 160-170 m, a drifter's efficiency being 9 m. Yet, at Kryvbas, monthly crosscut driving does not officially exceed 70 m according to official designs. This is a very low rate even for traditional drifting methods. Application of self-propelled equipment can help accelerate it.

So, selection of a technology of driving workings is of great importance. Choice of highly efficient machinery and technology is conditioned by both mining and geological conditions and required rates of drifting operations and their costs.

Main mining and geological factors include: ore rock hardness and stability, deposit dimensions along the strike, dip and thickness, deposit morphology, hydrogeological conditions, sometimes gas conditions, explosion risks, spontaneous ignition, radioactivity, etc.

At present, Kryvbas has started the second experiment of introducing self-propelled machinery in underground conditions. Let us consider the case of the underground mine "Oktiabrskaya", the PJSC "Kryvbaszalizrudkom", where the ore body "Osnovnyi" is mined applying self-propelled equipment in compliance with the "Project of development and stoping operations in the block between axes 45-50 on the level 1190/2265 m".

The ore body site within these axes is situated in the central part of the field of the underground mine "Oktiabrskaya" and limited to rocks of the V ferruginous and V schistose stratigraphic horizons.

The deposit is represented by the seam-like ore body which is uniform along the strike and weakly varying to the dip with inter-mineral impurities. Horizontal thickness of the ore body varies within 15-25 m. The ore body dip varies from 46˚ to 50˚. Its dimensions and shape refer the ore body to group "I", subgroup "b". Required prospecting intervals are 12-15 m along the strike, 25-30 m to the dip.

This part of the deposit is represented by: martite ore of the V ferruginous horizon, steel blue, fine-grained, thin-layered, badly fractured, with hardness of 5-7 and low stability; red dirt and martite ore of the V ferruginous horizon, grey-brown, represented by alternation of martite layers and dirt bands, of medium bedded structure, badly fractured, with hardness of 5-6 and low stability; red dirt of the V schistose horizon, dark-brown, coarsely-stratified, badly fractured, with hardness of 4-6 and low stability. Due to their instability, large hang-ups and rockfalls are possible. The ores do not tend to stick or drift, they are not rock-bump hazardous, cavities are not expected [15,57-59].

Many researchers note that mining enterprises use various type-dimensions of self-propelled machines. Main types of mining and transportation machines are used for mechanizing principal mining processes [13,20-22]. Efficient haulage length makes 250-300 m. The haulage workings dip is 10-15˚.

Most of sources mention dip angles of 10-15˚. In our opinion, such angles are borderline for now. The technological radius of roundings is 8-12 m.

As a rule, self-propelled load-haul machines are used in ore underground mines for preparatory operations and stoping.

At present, at underground mines of Kryvbas, broken ore is transported in stopes by scraper winches. They are

https://doi.org/10.1051/e3sconf/202128008010

also used when driving horizontal and inclined workings, especially on sublevels.

When it is not expedient to use scraper winches, self-propelled equipment is applied, e.g. on main haulage levels.

Scraper winches are obviously more advantageous in loading and hauling broken ore due to their relative structural simplicity and reliability in complicated mining and geological conditions.

Disadvantages of scraper winches include low efficiency and restricted haulage distance as well as quick rope wear and insufficient mechanization of operations.

For conditions of the underground mine “Oktiabrskaya”, scraper haulage is an obsolete technology that does not allow implementation of innovative ones and, therefore, decrease of mining costs.

Scraper haulage operations mechanization is beneath criticism.

That is why, mechanization of underground mining processes require self-propelled machinery for most difficult and labor-intensive operations. At advanced mines, this type of equipment is used for less labor-intensive auxiliary processes.

Highly efficient loading machines with large bucket capacity are used for mining large deposits.

Swedish mines, which are the most advanced in Europe, prove expediency and high efficiency of applying SCOOPTRAM to underground stoping operations.

The problem of enhancement of leading mines with the most promising mining systems applying self-propelled load-haul machinery is considered in [23-26].

Most advanced mining countries of the world tend to change over to stoping systems with backfilling of the mined space with a solidifying mixture. Room-and-pillar systems with backfilling are the most promising ones. The systems enable undisturbed daylight surfaces and enhanced environment due to possible disposal of mining wastes in dead areas of underground mines.

Modern load-haul machinery is often equipped with remote control systems. Remote control stations can be located at any distance from the place of mining operations. Automated operation of self-propelled load-haul equipment is applied at underground mines of South Africa.

Technologies of remote control application are described in many works [6,12,27,28, etc.]. Remote control of self-propelled machinery is implemented at advanced mining enterprises, including broken ore loading and transportation to discharge points.

Productivity of load-haul machines depends on their parameters and may reach 350-400 t/h with transportation for up to 50 m.

At world’s advanced underground mines, processes of ore loading and haulage are automated with modern equipment with dedicated hardware and software, thus increasing efficiency of self-propelled mining machines. Here, a mining engineer’s task consists in safe, efficient and profitable delivery of useful minerals to the daylight surface.

Describes use of underground haulers with 50t capacity in gold mining. The authors stress the necessity of implementing high-level mechanization of all ore mining operations [29-32]. Thus, according to the authors, the tunneling speed of up to 150 m/month is achieved due to application of three “Boomer” drilling rigs. The authors note that the latest models of the rigs are shortened from 4.2 m to 3 m. This enables the rigs to drill anchor holes in roofs with subsequent anchoring.

It should be noted that in conditions of highly intensive work, maintainability of mining equipment and ease of maintenance of self-propelled mining machines are of great importance.

Let us select and substantiate rational stoping parameters for sublevel-and-room mining at the u/m “Oktiabrskaya”, the PJSC “KZRK”. Considering mining and geological conditions of the ore body “Osnovnyi”, physical and mechanical properties of ore and country rock, the sublevel-and-room mining system is accepted for mining the ore body “Osnovnyi” of the u/m “Oktiabrskaya” minefield. Ore breaking is performed by vertical blasthole rings on the vertical slot. The sublevel-and-room mining system is designed for use of self-propelled mining machinery.

The input data for calculating block geometry are given in Table 1.

Table 1. Input data for calculating block parameters

No.	Input data	Parameters
1	Ore body class	II
2	Order of priority	I
3	Ore hardness, average	5.86
4	Hanging wall ore hardness	8-10
5	Ore body dip angle, degrees	42-50
6	Horizontal thickness, m, average	23
7	Normal thickness, m, average	18
8	Mining depth, m	1220
9	Sublevel height, m	40
10	Compensation room life	1.1

To determine geometry of the sublevel-and-room system, the following conventional signs are accepted:

$H_г$ and $H_в$ are the depth of horizontal exposures (crown) and vertical exposures (intervening pillars), m;

$f_р$ and $f_{пп}$ are ore hardness and rock hardness coefficients respectively;

$m_г^0$ is the boundary value of the equivalent span of the horizontal exposure in the stope, life of which in the set mining and geological conditions makes t months, m;

t is the exposure life;

$m_В^0$ is the boundary value of the equivalent span of the vertical exposure in the stope, life of which in the set mining and geological conditions makes t months, m;

η_1 and η_2 are the coefficients considering time impacts on stability of exposures and pillars;

η_3 is the coefficient describing relations between boundary values of equivalent spans of horizontal and vertical exposures;

$\ell_н^0$ is the boundary value of the equivalent span of the inclined exposure of the hanging wall rocks in the stope, life of which in the set mining and geological conditions makes t months, m;

$A_Н^0$, A_I^0, A_P^0 are the boundary values of dimensionless functional characteristics for determining horizontal (inclined) thickness of the crown and width of the intervening pillar, life of which in the set mining and geological conditions makes t months.

Let us determine boundary values of calculated functional characteristics: with the mining depth $H_г$ = 1180 m and hardness f_p = 6; $m_г^0 = 15.3$ m at $t = 6$ months.

At $t = 2$ months and $\eta_1 = 1.24$ (according to the chart by curve 1), Fig. 1:

By the formula:

$$m_г^0 = m_г^0 \cdot \eta_1 = 15.3 \cdot 1.24 = 19 \text{ m}$$

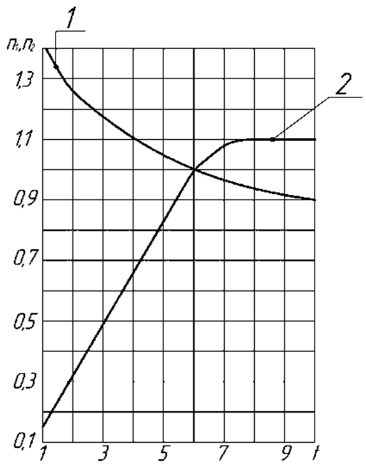

Fig. 1. Dependency of the coefficients η1 and η2 on life of exposures and pillars.

For $H_г$ = 1180 m and f_p = 6 (according to the chart, Fig. 2):

$$A_{ПР}^0 = 1.28 \text{ at } t = 6 \text{ months}$$

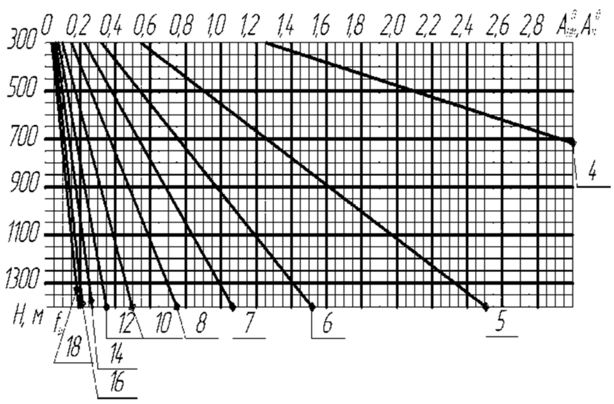

Fig. 2. Dependency of the boundary values of calculated functional characteristics $A_{Ц}^0$ and $A_{ПН}^0$ on the mining depth at t = 6 months.

At $t = 2$ months and $\eta_2 = 0.32$ (by curve 2)

By the formula:

$$A_{ПН}^0 = \eta_2 \cdot A_{ПН}^0 = 0.32 \cdot 1.28 = 0.41$$

To determine $m_В^0$ according to the formula:

$$m_В^0 = \eta_3 \cdot m_г^0$$

we find $m_г^0$ for $H_В$ = 1200 m and f_p = 6 at $t = 6$ months

$$m_г^0 = 15.1 \text{ m}$$

At $t = 6$ months, at $t = 2$ months and $\eta_1 = 1.24$

$$m_г^0 = \eta_1 \cdot m_г^0 = 1.24 \cdot 15.1 = 18.7 \text{ m}$$

$\eta_3 = 1.28$ then:

$$m_В^0 = 1.28 \cdot 18.7 = 24 \text{ m}$$

To determine $\ell_н^0$ by the expression:

$$\ell_н^0 = 1.35 \cdot m_г^0$$

we find $m_г^0$ for $H_В$ =1200 m and $f_{пп}$ = 9. From the chart $m_г^0$ = 20.5 m at $t = 6$ months. At $t = 2$ months and $\eta_1 = 1.24$

$$m_г^0 = \eta_1 \cdot m_г^0 = 1.24 \cdot 20.5 = 25.42 \text{ m}$$

$$\ell_н^0 = 1.35 \cdot 25.42 = 34.3 \text{ m}$$

By the formula:

$$A_п^0 = \frac{A_{пн}^0}{0.75} = \frac{0.41}{0.75} = 0.55$$

we determine geometric parameters of the mining system.

Dimensions of the stope along the strike are calculated applying the found value $m_г^0 = 19$ m and the known value of the horizontal thickness $M_г$ = 23 m from the left part of the chart a = 34 m; let us assume a = 30 m.

Dimensions of the stope to the dip are calculated applying the found value $m_В^0 = 24$ m and the known value of the normal thickness $M_н$ = 18 m; $в = \infty$.

The equivalent span of the hanging wall exposures in the stope is determined by the expression:

$$\ell_Н = \frac{a \cdot в}{\sqrt{a^2 + в^2}} = \frac{30 \cdot 23}{\sqrt{30^2 + 23^2}} = \frac{690}{37.8} = 18.25 \text{ m}$$

On comparing it with $\ell_н^0 = 34.3$ m, we obtain $18.25 < 34.3$; thus, the parameters *a* and *в* remain unchanged.

In this case, sublevel-and-room and level-and-room mining systems can be applied.

According to the functional characteristics of the designed block, the crown thickness is accepted equal to $h = 15$ m.

As at the level of 1220 m the block is mined first, the width of the pillar is not determined.

The obtained dimensions of the constructive elements of the system are given in Table 2.

Table 2. Dimensions of the constructive elements of the sublevel-and-room system.

Block elements	Accepted	Calculated
Stope dimensions along the strike	30	34
Stope dimensions to the dip	23	∞
Trench undercut width, m	30	-
Compensation space volume, m3	2632	-
Stope volume, m3	10526	-
Hanging wall rock exposure area, m2	690	782
Ore massif thickness above stope (crown), m	15	15

For drilling, it is expedient to use self-propelled longhole drilling machines SIMBA of Atlas Copco. The massif is broken by vertical blasthole rings on the horizontal compensation space (trench undercut), Fig. 3.

According to the suggested circuit and considering the ore body thickness, which is 20-25 m, it is reasonable to start drilling from the drill drift driven in the footwall rock.

After forming the trench undercut, part of the broken ore is left on the draw level. The broken ore will further serve as a compensation cushion to prevent workings of the draw level from failure.

Ore is broken by layers with a millisecond delay between the adjacent layers.

Drilling and blasting parameters are calculated in compliance with the instructions [33-36].

Drilling and blasting parameters for mining a block with average ore hardness $f = 6$ are given in Table 3.

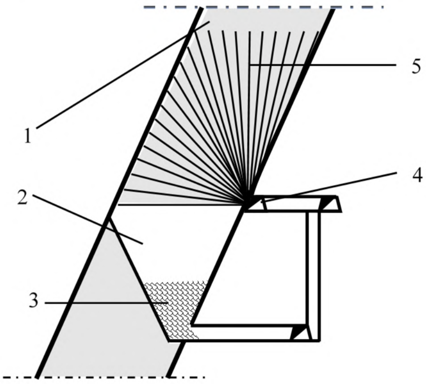

Fig. 3. The circuit of breaking the massif by vertical blasthole rings on the horizontal compensation space (trench undercut): 1 – the ore body, 2 – the trench undercut, 3 – the broken ore cushion, 4 – the drill drift, 5 – the blasthole ring.

The blasting and drilling parameters are calculated based on the practice of the underground mine "Oktiabrskaya". The LLR equals 3 m. The distance between hole ends is 3.5 m. In our opinion, such parameters will decrease oversize yield and losses of explosives for secondary fragmentation.

Table 3 Drilling and blasting parameters for mining the block under study.

Indicator	Units of measure-ment	By rock hardness	Conside-ring stress state
Rock blasting indicator	C_0	36.867	34.964
LLR value	m	3.5	3.38
Distance between blasthole ends	m	3.85	3.65
Boundary consumption of explosives for breaking	kg/t	0.318	0.302
Diameter of average ore fragment (fragmentation quality)	m	0.184	0.178
Oversize yield	%	13	12.6
Specific consumption of explosives for secondary fragmentation	g/t	75	74

The process water from drilling blastholes is gathered in the sludge trap of the drill drift. Then, it goes in metal and rubberized pipes of 2-3 inches in diameter to the sludge settler of the access ort where it is clarified. The clarified water runs to the drainage ditch of the haulage ort and then to the mineshaft into the water reservoir.

When drilling the ore massif above the trench undercut level from the drill drift, the process water from drilling blastholes is gathered in the sludge settler in access orts above the area of blasthole drilling for clarification. The clarified water is drained into the drainage ditch of the haulage drift and then to the mineshaft into the water reservoir.

Two versions of the rational draw level structure are suggested.

The first version of the draw level with application of modern load-haul machines for transporting broken ore is developed for the ore body thickness l of over 25-30 m, Fig. 4.

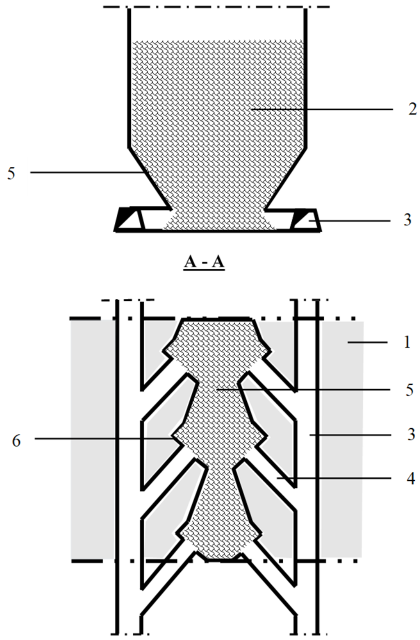

Fig. 4. The draw level structure for the ore body thickness of over 25-30 m with application of modern load-haul machinery for broken ore transportation: 1 – the ore body, 2 – the stope, 3 – the supply ort, 4 – the loading face, 5 – the trench undercut, 6 – the frontal loading face.

In this case, the stope 2 is located across the strike.

Block supply orts 3 from which loading faces 4 are driven at the angle to the stope are located on the boundaries of the block.

Block undercutting is trench. The trench 5 is created on the transportation level across the strike. The trench width should provide broken ore loading from the opposite loading faces.

The main disadvantage of loading broken ore from loading faces driven at the angle is that the bucket goes into the broken ore at the angle as well, thus deteriorating the bucket fill factor and resulting in one side wear of the bucket.

To eliminate this disadvantage, we suggest formation of the loading face 6 in the way that enables frontal fill of the bucket through its entering the muckpile perpendicularly.

The other option of the draw level with application of modern load-haul machines for transporting the broken ore is developed for the ore body thickness l of less than 25-30 m, Fig. 5. In this case, the stope 2 is located along the strike.

Block undercutting is trench. The trench 3 is created along the strike for the full width of the stope. The trench height depends on the thickness of the ore body and the angle of the trench slope dip which should provide broken ore rolling down the trench slopes by gravity.

In the footwall of the block, the block supply drift 4 is driven from which loading faces 5 are driven at the angle to the stope.

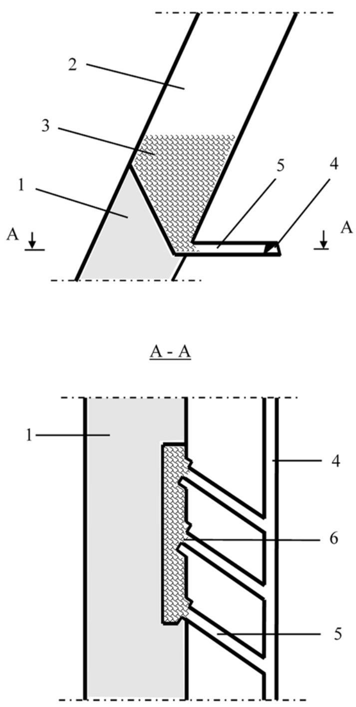

Fig. 5. The draw level structure for the ore body thickness of less than 25-30 m with application of modern load-haul machinery for broken ore transportation: 1 – the ore body, 2 – the stope, 3 – the trench undercut, 4 – the supply drift, 5 – the loading face, 6 – the frontal loading face.

The frontal loading face 6 is formed to enable frontal loading of the bucket through its entering the muckpile perpendicularly.

Considering the fact that the number of blocks at Kryvbas underground mines applying self-propelled equipment is limited, it is recommended to use self-propelled load-haul machines, previously used to drive workings, for broken ore transportation. With this purpose, we plan to use ST1030 SCOOPTRAM of Atlas Copco.

Ore can be discharged into both ore passes and electric railway haulage cars.

4 Conclusions

The work presents analysis of literature sources dealing with application of self-propelled machinery in stoping in general and for underground mining operations only and considers practices of mining enterprises' performance in similar conditions.

Geometry of block elements at stoping applying the sublevel-and-room system in compliance with the instructions "Determination and control of permissible dimensions of structural elements of mining systems at Kryvbas mines" is calculated to ensure stability of stopes throughout the block life.

The article suggests efficient versions of drilling the massif and determines their advantages and disadvantages.

The main disadvantage of loading the broken ore from loading faces driven at the angle is that the bucket of the machine enters the muckpile at the angle as well, thus deteriorating the bucket fill factor and resulting in one side wear of the bucket.

To eliminate this disadvantage, the authors suggest new versions of the draw level structure with formation of the loading face in the way that enables frontal fill of the bucket through its entering the muckpile perpendicularly and provide drawings of the versions.

The suggested enhanced technology of stoping considers the recommended parameters of underground operations on the basis of the research conducted.

The conducted research proves the viability of the developed technology and enable recommending its implementation.

Abstract. The main sources of methane emission are located in the undermined coal-bearing strata, which is not taken into account by the requirements of regulatory documents when determining the category hazard of coal mines. Gas emission from each undermined source is not equally dependent on the tons of coal mined. The relative gas emission changes during the cleaning work and cannot be a criterion for assessing the gas hazard of the entire mine. The volatility of the gas emission index per unit area of the underworked space, which was formed because of monthly movements of the working faces, was established. In essence, this indicator repeats the dependence of the relative gas content per ton of coal mined, since the area of the underworked space is functionally related to the amount of coal mined for a certain period. Without coal mining, the rate of movement of the working face is equal to zero, and gas emission from a unit area continues for several months. As a result, the considered indicators do not have their specific meaning and, due to their inconstancy, they cannot reliably reflect the gas hazard of mines.

1 Introduction

The regulatory framework for safe mining of gas-bearing coal seams was laid down in the 1960s. This concerns the establishment of hazard categories of mines [1] and predictions of gas emission during mining operations [2]. The development of the requirements of these documents was based on the assumption of a direct proportional relationship between the level of gas emission and the amount of coal produced. To some extent, this approach was justified by the fact that the main source of gas emission during the treatment was the underworked reservoir. The share of gas emission from the broken coal and the exposed surface of the working face, during that period of development of the Donbass coal deposits, was 60 ÷ 80% of the total gas balance of the mining area. Over the past several decades, mining operations have been forced to move to deeper levels. This caused a significant change in the gas balance of the working areas during the cleaning work. In modern mines when mining at a depth of 500 ÷ 1500m the main gas release up to 90% and more comes from the coal-bearing strata undermined by the workings. The level of gas emission from these sources (adjacent seams and enclosing rocks), in addition to coal mining, is influenced by other factors. These, first of all, include the processes of displacement of underworked rocks during the cleaning work [3]. Over the past, not only the main sources of methane emission have changed in quality and quantity, but also the factors that determine its level and methods of safe mining of gas-bearing coal seams [4-8]. Such changes in the conditions of mining operations have practically not been adequately reflected in the regulatory framework [1, 2], the provisions of which have not been revised for many years. For example, the gas hazard is confined only to the level of coal production, and the degree of development of cleaning work within the excavation area and the wing of the coalfield is not considered. Unfortunately, accidents with serious consequences associated with the ignition of gas-air mixtures and their explosions in coal mines recur periodically. This indicates the relevance of the works aimed at establishing the factors that determine safe development of gas-bearing coal seams.

2 Purpose, idea and research methodology

The aim of this subsection is to establish the main factors that determine methane emission throughout the entire period of mining areas exploitation. This makes it possible to determine the influence of the degree of cleaning works development on the associated processes of undermined coal-bearing strata displacement and gas emission. To develop proposals in terms of improving the forecast of gas emission and establishing the category hazard of mines.

The idea is that the level of methane emission and the total amount of gas emission from undermined sources depends both on the size of the extraction pillar and on the speed of moving the active face. Monitoring throughout the entire period of the mining operation allows to assess the change in gas emission during the cleaning operations (removal of the face from the open pit) at all characteristic stages of coal mining - reaching targets, stable operation and reducing the load before stopping the face.

The indicators of gas emission for a certain movement of the active faces for a fixed period of time, including the official monthly average data for establishing the category of mines by their gas hazard, are considered.

The well-known experimental data [4,5], obtained respectively in the conditions of the A.F. Zasyadko mine, and the Newspaper "Izvestia" mine, as well as monthly average data for establishing the category hazard of the "Sukhodolskaya-Vostochnaya" mine and the D.F. Melnikov mine over the past four to five years. Basic information about the objects of observation is summarized in Table 1. In all cases, the roof was controlled by the complete collapse of the rocks. Experimental data made it possible to establish the amount of gas emitted per time interval.

3 Research results and discussion

In all cases, in the initial period of the mining areas exploitation, as the working faces were removed from the split furnaces, an increase in the amount of emitted gas was observed (Fig. 1). The increase in methane emission during this period is due to an increase in the underworked space and the development of displacement processes of underworked rocks to the settlement of the main roof with the subsequent development of these processes. After the formation of a constant height of the zone of rock displacement with a rupture of their continuity, stabilization of gas emission occurs at a certain level. In most cases, before stopping the working face, its speed decreases.

As a rule, the minimum rates of the active faces' movement correspond to the initial and final periods of exploitation of extraction areas, which is due to the specific features of technological processes when mining coal seams with long faces. They are characterized by the need for grinding in mechanisms and identifying possible defects in equipment installation. For these reasons, sometime is required to ensure the planned performance of the extraction areas.

A decrease in the speed of moving the active faces before stopping them is determined by the transition period associated with the need to commission the next extraction pillar. For the organization of cleaning work in the newly commissioned face, additional material and human resources are required, as well as a certain period of time for reaching the planned indicators.

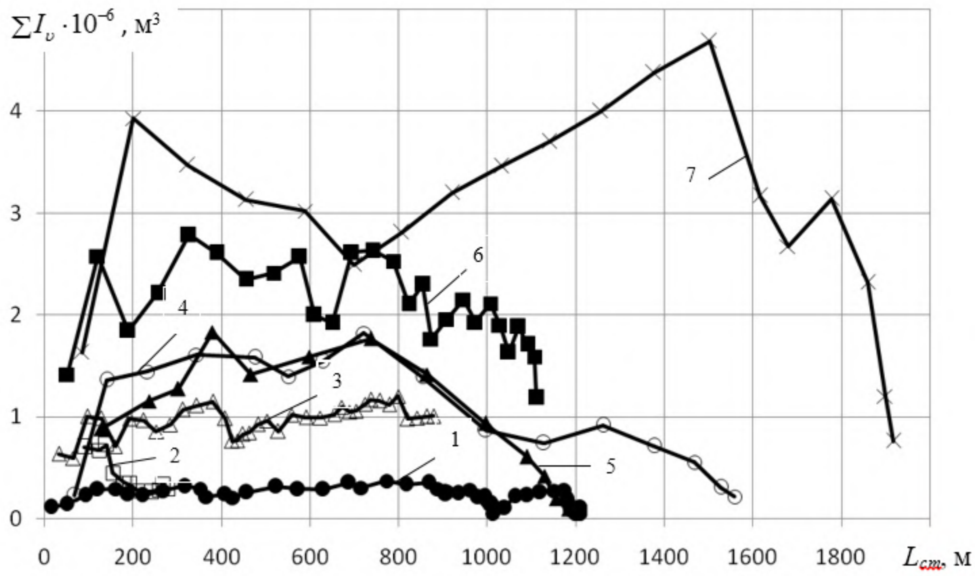

Fig. 1. Change in average monthly volumes of gas emission ($\sum I_{\upsilon}$) depending on the removal of active faces (L) from cut workings. 1, 2, 3, 4, 5, 6, 7 - graphs of changes in gas emission, respectively, for the D.F. Melnikov mine (1st northern face layer ℓ_6), the Newspaper "Izvestia" mine (2nd bis, 2nd and 3rd western faces of the seam $\ell_2^{в}$), "Sukhodolskaya-Vostochnaya" (12th bis and 24th eastern facfes of the seam i_3'), the A.F. Zasyadko mine (16th eastern seam m_3m_3); ●, □, ■, ○, ▲, Δ, × - experimental data.

Experimental data (Table 1, Fig. 1) shows that the volumes of the emitted gas depend on the dimensions of the extraction pillars. They are characterized by their length (L_{cm}) and the length of the exploited longwalls ($L_{л}$), as well as by the speed of active faces. This can be seen in the example of the Newspaper "Izvestia" mine faces. In the section of the 2nd bis of the western face (curve 2) with a pillar length of 279 m. and the speed of moving the active face 9÷41 m/month. much less gas was emitted in comparison with the 2nd (curve 3) and 3rd (curve 4) western faces, for which the value of L_{cm} was 1186 and 1559 m, respectively, and $\upsilon_{оч}$ -27÷139 and 31÷144 m/month.

The influence of the active faces movement rate on the values $\sum I_{\upsilon_{\text{очі}}}$ is also confirmed by experimental data for the 12th bis (curve 5) and 24th (curve 6) eastern faces of the "Sukhodolskaya-Vostochnaya" mine. With the same length of faces (240m) in the section of the 24th eastern face and $\upsilon_{оч}$ = 5÷70 m/month, 50.5 million m^3 of gas was emitted (Table 1), and in the section of the 12th bis eastern face at $\upsilon_{оч}$ = 12-36 m^3/month only 34.8 million m^3 of methane was emitted.

The above facts indicate that gas emission is associated both with the size of the area of the underworked face space (S_{cm}= $L_{л}$×L_{cm}), and with the speed of the active faces movement ($\upsilon_{оч}$). In addition to the specified technological parameters (S_{cm}, $\upsilon_{оч}$), other factors also affect gas emission from the undermined strata. First of all, they should include the reserves (resources) of methane, which is in the coal-rock strata before the cleaning works. Preliminarily, the estimated gas reserves can be judged by the gas content of the coal in the developed seams. Natural gas content of seam m_3 (the A.F. Zasyadko mine) is 35 m^3/t.m.a.m., seam i_3' (the "Sukhodolskaya-Vostochnaya" mine) - 33 m^3/t.m.a.m. When underworking the $\ell_2^{в}$ seam, the Newspaper "Izvestia" mine, its natural gas content decreased from 35 to 3÷8 m^3/ t.m.a.m. as the pillars were underworked along the uprising and the active faces approached the zone of gas weathering and geological disturbance (Karlovsky discharge). The natural gas content of the ℓ_6 seam (the D.F. Melnikov mine) did not exceed 8 m^3/ t.m.a.m. This ratio of natural gas content of the underworked seams obviously influenced the amount of gas emitted from the undermined coal-rock strata (Table 1, Fig. 1). The question of the possible volumes and forms of gas occurrence in the coal-bearing strata requires a separate detailed study.

The influence of the active faces movement rate ($\upsilon_{оч}$) on the amount of gas emitted from the undermined strata (I_{υ}) manifested itself in the form of differing dependencies for different objects (Fig. 2, a). During the development of the m_3 seam, a directly proportional dependence was observed (straight line 2), and during the extraction of the i_3 and ℓ_6 seams, an exponential dependence (curves 1 and 3, respectively).

When underworking the $\ell_2^{в}$ seam, the trend of dependence $I_{\upsilon} = f(\upsilon_{оч})$ also approaches exponential (Fig. 2, b). Large deviations of the experimental data from the averaging curve are caused by significant differences in gas resources in the undermined massif during the development of individual pillars due to the influence of geological disturbances, different degrees of cleaning works in the wing of the mine field, and the presence of gas emission outside some extraction areas under the influence of the activation of rock displacement.

In the presence of additional sources outside the extraction areas, ventilation schemes were used, which contributed to an additional flow of gas into the area workings. The given results of mine observations indicate that in order to ensure the safe development of gas-bearing coal seams, along with technological factors (L_{cm}, $L_{л}$, S_{υ}', $\upsilon_{оч}$) and natural gas resources in the undermined strata, it is necessary when designing ventilation schemes for extraction areas to provide for the exclusion of gas from external sources under the influence of general mine depression.

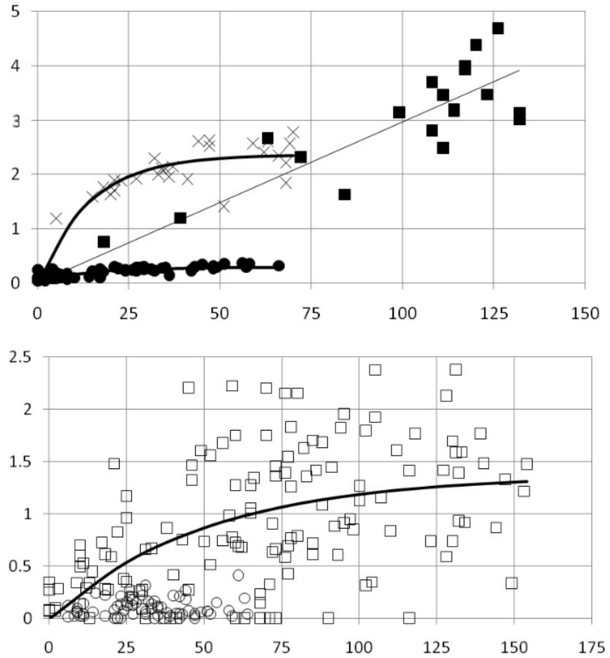

Fig. 2. Dependence of the released amount of gas (I_υ) from the undermined coal-rock strata on the active faces movement rate ($\upsilon_{оч}$) under conditions of different mines. 1, 2, 3, 4 - averaging lines, respectively, for the experimental data of the “Sukhodolskaya-Vostochnaya” mine (24th eastern face, seam i_3'), the A.F. Zasyadko mine (16th eastern face, seam $т_3$ [9]), the D.F. Melnikov mine (1st northern face, layer ℓ_6), the Newspaper “Izvestia” mine (2nd bis and 2-9th western faces, seam $\ell_2^в$ [10]); ×, ■, ●, □ - experimental data for averaging lines; ○ - experimental data for the 1st and 1st bis of the western faces of the Newspaper “Izvestia” mine located directly in the zone of geological disturbance; *R*, *r* - correlation ratio and correlation coefficient, respectively.

Of scientific and practical interest is the dependence of gas emission per unit area of undermined space ($\frac{I_\upsilon}{S_\upsilon'}$) on the active faces movement rate ($\upsilon_{оч}$). The $\frac{I_\upsilon}{S_\upsilon'}$ indicator is insufficiently studied to date. The graphs of such dependencies (Fig. 3) show the variability of this parameter for each object of observation. In essence, the $\frac{I_\upsilon}{S_\upsilon'}$=*f*($\upsilon_{оч}$) dependence repeats the dependence of the relative gas abundance per ton of coal mined, since the area (S_υ') for each mining area is functionally related to the amount of coal mined for a certain period of time. In the absence of coal mining ($\upsilon_{оч}$=0), gas emission per unit area of the worked-out area does not have its specific meaning, since the value of this parameter tends to infinity. This is due to the presence of gas emission from underworked sources for a long time (several months) when the active face is stopped ($\upsilon_{оч}$=0). The above circumstances do not allow the $\frac{I_\upsilon}{S_\upsilon'}$ indicator to be used as a criterion for gas hazard in the course of cleaning work.

For practical purposes, the most suitable parameter for assessing the gas hazard may be the gas e4mission indicator $\sum I_{cm}^i$, which characterizes the total amount of gas emitted from the undermined sources from the start of operation of the extraction area to the current moment.

The main advantage of the $\sum I_{ст}^i$ indicator is its functional dependence for specific extraction areas. The $\sum I_{ст}^i$ parameter unambiguously increases as the working faces (*L*) move away from the split working (Fig. 4, a). In a similar way, the $\sum I_{cm}^i$ indicator depends on the area of the underworked space (Fig. 4, b).

The given graphs indicate that under unchanged geological and mining-engineering conditions, the total amount of emitted gas changes in direct proportion as the length of the underworked pillar increases (Fig. 4, a) or the area of the underworked space (Fig. 4, b). This dependence was unambiguously characteristic of the extraction areas of the D.F. Melnikov mine (line 1) and the A.F. Zasyadko mine (line 3), where mining and geological conditions did not change as the mining pillars were worked out. In the conditions of the mine. The Newspaper “Izvestia” mine found a deviation of experimental data (curve 2) from a directly proportional relationship (line 2 '), which is caused by a decrease in gas reserves in the underworked strata as the active faces move away from cut workings and approach the zone of gas weathering or geological disturbance. Despite the changes in the mining and geological conditions of the working areas during the development of the $\ell_2^в$ seam, a close correlation was established (r = 0.97) of the amount of emitted gas on the area of the underworked space of individual working areas (Fig. 5).

As the active faces of the 12th bis and 24th eastern faces moved away from the split furnaces (“Sukhodolskaya-Vostochnaya” mine), the experimental data $\sum I_\upsilon^i$ (curve 4) deviated from the directly proportional relationship upward (Fig. 4, line 4). This indicates a change in mining and geological conditions and an increase in the amount of gas per unit of undermined area. Knowing the $\sum I_\upsilon^i$ change, when removing stope from cut workings (*L*) or an increasing area of undermined space (${S'}_\upsilon^i$), it is not difficult to reliably predict gas emission for any stage of development of the next extraction pillars. The obtained results of experimental data processing indicate that for specific geological and mining-engineering conditions, a reliable indicator of gas hazard can be the ratio of the total amount of emitted gas, referred to the area of the extraction pillar being underworked at the current time or the end of the cleaning work in the extraction pillar. The change in the $\frac{\sum I_\upsilon^i}{\sum {S'}_\upsilon^i}$ indicator in the initial period of the excavation areas operations is associated with the removal of the active faces from the cut workings (*L*) and the development of the processes of displacement of the undermined rocks with subsequent precipitation of the main roof. With sufficient removal of the active face (*L*), stabilization occurs, if the geological and mining-engineering conditions of the excavation areas exploitation do not change (Fig. 6). This type of change $\frac{\sum I_\upsilon^i}{\sum {S'}_\upsilon^i}$ was observed for the faces of the D.F. Melnikov (curve 1) and the A.F. Zasyadko mines (curve 6).

In the conditions of the Newspaper “Izvestia” mine,

 https://doi.org/10.1051/e3sconf/202128008011

this kind of dependence was established for the extraction pillars of the 3rd (curve 3) and 2nd (curve 4) western faces (Fig. 6). The length of these extraction pillars was, respectively, 1559 and 1186 m, which made it possible to stabilize the processes of rock displacement when the active faces were removed from the cut workings at a distance of more than 250÷350 m, and together with them to reach approximately constant values for the indicator $\frac{\sum I_\upsilon^i}{\sum S'^{i}_\upsilon}$.

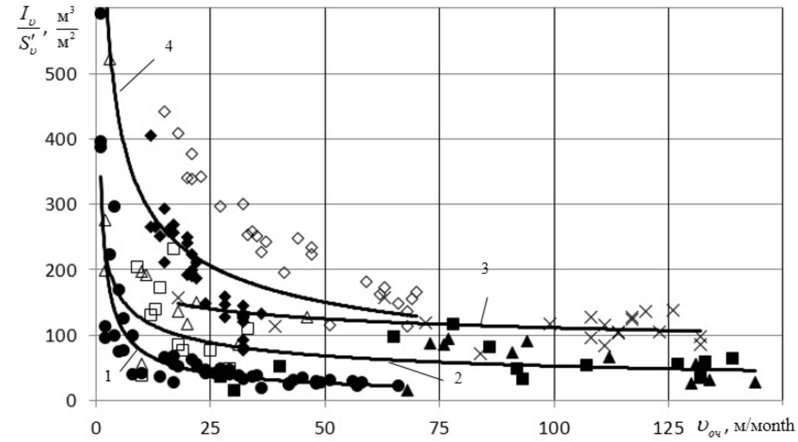

Fig. 3. The dependence of the specific gas emission in relation to the unit of area of the worked-out space ($\frac{I_\upsilon}{S'_\upsilon}$), corresponding to the monthly rate active faces movement ($\upsilon_{оч}$). 1, 2, 3, 4 - averaging curves, respectively, for the D.F. Melnikov mine (1st northern face, seam ℓ_6), the Newspaper "Izvestia" mine (2nd bis, 2nd, 3rd, 9th western faces, same $\ell_2^{в}$), the A.F. Zasyadko mine (16th eastern face, seam $т_3$), "Sukhodolskaya-Vostochnaya" (12th bis, 24th eastern face, seam i_3').

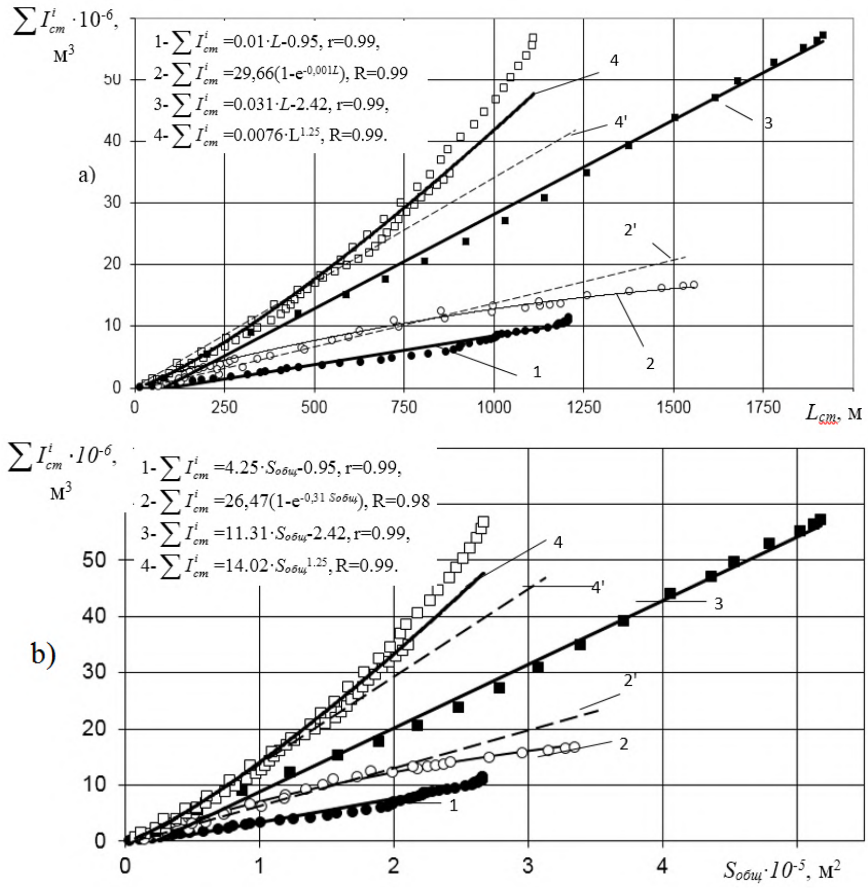

Fig. 4. Dependence of the total amount of gas emitted from the undermined coal-rock strata ($\sum I_\upsilon^i$) as the active face (a) moves (L) and the area (S_{cm}) of the worked-out space (b) increases. 1, 2, 3, 4 - averaging lines, respectively, for the D.F. Melnikov mine (1st northern face, seam ℓ_6), the Newspaper "Izvestia" mine (2nd bis, 2nd, 3rd western faces, seam $\ell_2^{в}$), the A.F. Zasyadko mine (16th eastern seam $т_3$), and the "Sukhodolskaya-Vostochnaya" mine (12th bis, 24th eastern faces, seam i_3'); 2', 4' - predicted direct $\sum I_{cm}$ dependencies for unchanged mining and geological conditions in comparison with the beginning of the exploitation of extraction areas, respectively, for the faces of the Newspaper "Izvestia" and "Sukhodolskaya-Vostochnaya" mines; ●, ○, ■, □ - experimental data; r, R - correlation coefficient and correlation ratio, respectively.

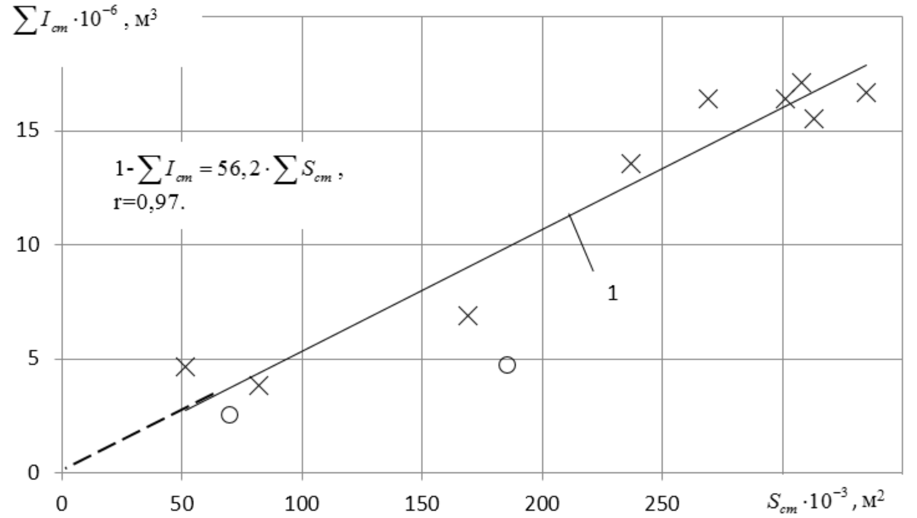

Fig. 5. Dependence of the amount of released gas ($\sum I_{cm}$) within the excavation areas of the Newspaper "Izvestia" mine from the area of underworked spaces of stopped faces (S_{cm}). 1- averaging line for faces located outside the immediate zone of geological disturbances; r - correlation coefficient; × - experimental data for faces (2nd, 2nd bis, 3rd, 4th, 5th, 6th, 7th, 8th, 9th) outside the zone of direct influence of geological violations; ○ - experimental data for faces (1st and 1st bis) in the immediate zone of influence of geological disturbances.

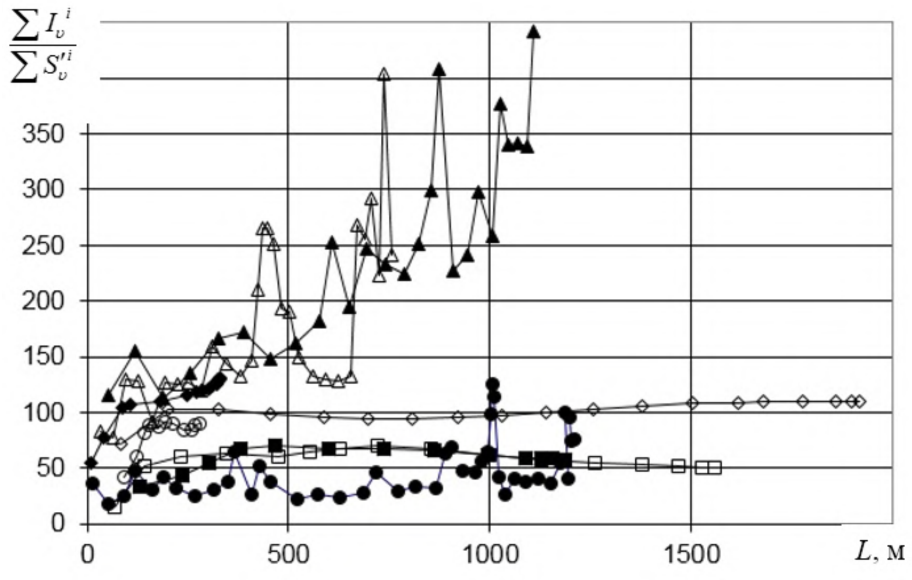

Fig. 6. Change in the specific gas emission relative to a unit area of the underworked space of the extraction pillars ($\frac{\sum I_{\upsilon}^{i}}{\sum S'^{i}_{\upsilon}}$) when removing ($L$) the active faces from the cut workings. 1,2,3,4,5,6,7,8 - curves of the $\frac{\sum I_{\upsilon}^{i}}{\sum S'^{i}_{\upsilon}}$ indicator change, respectively, in the conditions of the D.F. Melnikov mine (1st northern face, seam ℓ_6), the Newspaper "Izvestia" mine (2nd bis, 2nd, 3rd, 9th western faces, seam $\ell_2^{в}$), the A.F. Zasyadko mine (16th eastern face, seam $т_3$), the "Sukhodolskaya-Vostochnaya" mine (24th, 12th bis eastern faces, seam i_3'); ●, ○, ■, □, ♦, ◊, ▲, Δ - experimental data.

During the operation of the 2nd bis (curve 2) and 9th (curve 5) western faces, there was no opportunity for the development of rock displacement processes to such an extent, since the length of their extraction pillars was, respectively, only 279 and 329m. For this reason, during mining of faces with short pillars only showed an increase in $\frac{\sum I_{\upsilon}^{i}}{\sum S'^{i}_{\upsilon}}$ values to a certain level without their further stabilization. It should be noted that the average advance velocity of the 2nd bis and 9th western faces for the entire period of their mining was insignificant and amounted to 0.7 and 0.9 m/day, respectively. In the mining areas of these faces, during the period of operation, 4.7 and 4.4 million m^3 of methane were emitted into mine workings and degassing wells, respectively. At approximately the same rate of movement ($\upsilon_{оч}$) and the amount of emitted gas ($\sum I_{\upsilon}^{i}$), the change in the $\frac{\sum I_{\upsilon}^{i}}{\sum S'^{i}_{\upsilon}}$ parameter curves (Fig. 6, curves 5 and 2) as the working faces moved away from the cut workings significantly differed from each other.

After stopping the faces, the $\frac{\sum I_v^i}{\sum S'^i_v}$ indicator for these faces was respectively 90.4 and 53.9 m^3/m^2. This difference is explained by the distinctive features of face exploitation. The length of the 2nd bis of the western face was 185 m, and the 9th western face was 250 m. With little differing average rates of moving faces (0.7 and 0.9 m/day) and the length of the pillars (279 and 329 m), the area the underworked spaces of the considered faces differed by more than 1.5 times (51.6 and 82.3 thousand m^2). The natural gas content of the underworked seam during the operation of the 2nd bis of the western face was 24.0 м^3/t.m.a.m., and during the development of the 9th western face - 35.0 м^3/t.m.a.m. This indicates that the gas resources in the undermined coal-bearing strata of the 9th western face should have been approximately one and a half times higher than the $\frac{I_{ст}}{S'_{ст}}$ indicator for the 2nd bis of the western face. If, in addition to the natural gas content of the developed reservoir, we also consider the area of the underworked pillars, then the total gas emission $I_{ст}$ in the 9th western section should have been 2.3 times higher than this indicator for the 2nd bis of the western face. The experimental data did not confirm such a relation between $I_{ст}$ and $\frac{I_{ст}}{S'_{ст}}$. The $I_{ст}$ indicator for both faces was approximately the same, and $\frac{I_{ст}}{S'_{ст}}$ for the 2nd bis of the western face it was almost 1.7 times higher than its value for the 9th western face. The obtained experimental data can only be explained by the sequence of mining of these faces. The extraction pillar of the 2nd bis of the western face during its mining was isolated from all sides by a coal mass, and the extraction pillar of the 9th western face was adjacent to the underworked area of the previously mined ten faces. In the first case, gas was emitted only within the mining area, and in the second, due to the direction of the depression, it was carried out from the local workings to the general mine. In the conditions of the "Sukhodolskaya-Vostochnaya" mine when the active faces of the 24th (curve 7) and 12th bis (curve 8) eastern faces of the seam i'_3 (Fig. 5) were removed from the cut workings, the change in the values of the $\frac{\sum I_v^i}{\sum S'^i_v}$ indicator was approximately the same. This indicates that for these faces, geological and mining-engineering conditions change in approximately the same way during the development of cleaning works.

If the area of the underworked space (S'^i_y), which was formed during the monthly movement of the active face ($v^i_{оч}$), is less than the area of the underworked space $\sum S_v^i$, which determines the gas emission $\sum I_v^i$, then the $\frac{I_v^i}{S}{'}^{i}_{v}$ value will always be greater then $\frac{I_v^i}{\sum S'^i_v}$. The equality of these indicators is possible only for cases when the monthly rate of active faces movement ensures the extraction of the formation in an area corresponding to the size of the gas emission zone. The dimensions of the gas emission zone above the active face are determined by the zones of active movement of the undermined rocks. The projection of the size of such a zone behind the active face according to [3] is 0.466 of the depth (*H*) of the cleaning work. For example, for the conditions of the Newspaper "Izvestia" mine, the gas emission zone behind the active face is about 140 m, and for the conditions of the A.F. Zasyadko mine - about 550 m. The maximum speed of active faces movement of about 140 m/month was provided in some months only for several faces (2nd, 3rd, 4th, 5th western) of the Newspaper "Izvestia" mine. For these cases, the values of $\frac{I_v^i}{S}{'}^{i}_{v}$ and $\frac{I_v^i}{\sum S'^i_v}$ in all cases were close to each other, which confirms the reliability of determining the size of active movement zones of underworked rocks and the corresponding dimensions of the underworked space, which determine gas emission from the coal-rock strata.

On the site of the 16th eastern face of the m_3 seam of the A.F. Zasyadko mine the reached speeds (132 m/month) of the active face (Table 1) were significantly less than the projection of the active movement zone of rocks behind the active face. This, obviously, predetermined higher $\frac{I_v^i}{S}{'}^{i}_{v}$ values in all cases compared to $\frac{I_v^i}{\sum S'^i_v}$ after removal of the active face from the cut working at a distance of more than 550 m. Confirmation of the coincidence of the sizes of gas evolution zones with zones of active rock movement requires additional research.

4 Conclusions

Based on the generalization of the results of the studies carried out to establish the main factors of gas hazard in coal mines of Ukraine, the following conclusions have been drawn:

- the regulatory framework for safe mining of gas-bearing coal seams is based on research carried out 50÷60 years ago. Over the past, due to the transition to deeper layers, the gas balance and the sources of methane emission during the cleaning work have changed significantly. In modern mines, the main share of gas emission comes from the undermined coal-rock strata, and the requirements of regulatory framework for the establishment of gas hazard are focused on directly proportional dependence on the level of coal production from the underworked seam. The change in the gas balance and the share of the main sources of methane emission of its constituents led to a change in the factors that determine the danger of mining operations based on the gas factor. The provisions of the regulatory framework regarding the determination of the gas hazard and the forecast of gas emission have not been revised for several decades;
- the total amount of gas emitted from the undermined coal-rock strata, all other things being equal, directly depends on the area of the undermined space of the mined extraction pillars;
- the current level of gas emission depends both on the resources of methane in the undermined sources, and on the rate of the active face movement. The total amount of emitted methane remains constant for the specific dimensions of the mining field;

- the indicator of the amount of gas emitted per unit area of the undermined space, formed in the process of a monthly movement of the active face, is not a constant parameter for specific mining and geological and mining conditions. This is due to the non-coincidence, in most cases, of the active faces movement speed for a certain period of time (a month) with the sizes of the gas emission zones from the undermining array after the passage of the active face. The change in this indicator is similar to the dependence of gas emission per ton of coal mined. For this reason, it cannot be a criterion for assessing the gas hazard in mines;
- with sufficient development of cleaning works in the mine field, additional sources of gas emission appear outside the exploited working area under the influence of the activation of the undermined rocks movement. This phenomenon must be taken into account when designing ventilation schemes for mining areas and the direction of action of a general mine depression.

The scientific results obtained make it possible to develop a new methodology for assessing the gas hazard in coal mines and predicting gas emission from the undermined coal-rock strata based on the existing production experience and technical documentation for establishing the hazard category of coal enterprises in previous years in accordance with the regulatory framework in force at that time.

Abstract. The purpose of this article is to present modern approaches to data storage and processing, as well as technologies to achieve the quality of data needed for specific purposes in the mining industry. The data format looks at NoSQL and NewSQL technologies, with the focus shifting from the use of common solutions (traditional RDBMS) to specific ones aimed at integrating data into industrial information systems. The information systems used in the mining industry are characterized by their specificity and diversity, which is a prerequisite for the integration of NoSQL data models in it due to their flexibility. In modern industrial information systems, data is considered high-quality if it actually reflects the described object and serves to make effective management decisions. The article also discusses the criteria for data quality from the point of view of information technology and that of its users. Technologies are also presented, providing an optimal set of necessary functions that ensure the desired quality of data in the information systems applicable in the industry. The format and quality of data in client-server based information systems is of particular importance, especially in the dynamics of data input and processing in information systems used in the mining industry.

Introduction

Modern databases, which are the basis of information systems, operate with different data models. The aim is to represent them to describe the described real objects as accurately as possible, and the challenge is at the same time for the data form to allow their online processing in real time (Fig. 1).

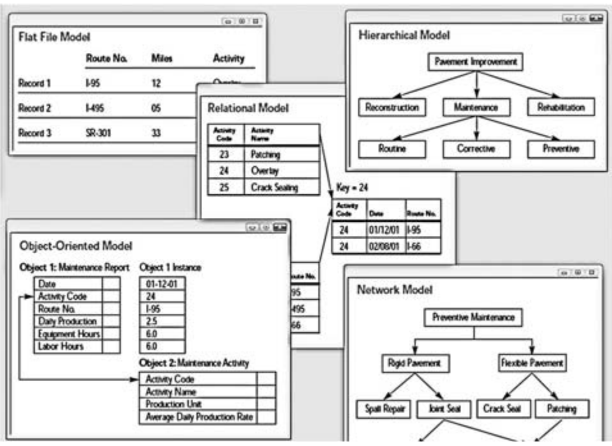

Fig. 1. Database models.

In general, the evolution of database management systems (DBMS) can be described in three stages:

- Navigation systems - those were used in the 1960s and represented hierarchical and network models of data description;
- Relational - those were created in the 1970s and are used to this day. They are based on set theory and on relational algebra. The objects are described in the form of two-dimensional tables allowing for connections (relations) between them. They use the SQL programming language;
- Post-relational - this category comprises a wide variety of data description methods. The object-oriented model was introduced in the 1980s, and the NoSQL and the NewSQL models have become popular in the recent decade.

Over the past 10 years, NoSQL and NewSQL models have become popular, which are targeting for a specific problem, such as short-term OLTP (Online Transaction Processing) operations.

At the same time, the information in them should be as high-up to date, accurate and sufficiently comprehensive as possible to enable maximum effective solutions.

In the mining industry, the processes are in continuous dynamics, mutually connected, and each of them can affect the operation of the whole system, depend also on the natural resources and require large investments in resources and funds. Moreover, the majority of the tasks in the modern mining industry are characterized by a pronounced uncertainty, non-linearity and multifactorial. [1] In this case, an unfortunate decision taken based on poor quality information can lead to huge losses for the particular enterprise.

In order to avoid such situations, it is especially important to obtain quality data, i.e. data meeting the

* Corresponding author: yordanka.anastasova@mgu.bg

https://doi.org/10.1051/e3sconf/202128008012

requirements of the specific information system. The format and quality of the data is directly dependent on the purposes for which they will be used [2], and from the point of view of information systems the format and quality of the data is part of the whole process of data management.

Modern data models

Standard relational databases were not designed to handle the scale (Big Data), flexibility and real-time operation that are required by modern information systems. In addition, they do not take full advantage of the low cost of storage devices, nor of the high performance of the machines we have at our disposal nowadays.

NoSQL encompasses a wide variety of database technologies that have been developed in response to the increasing amount of data stored for users, objects and products, the frequency with which this data is accessed, as well as the need of high performance in their processing.

The first NoSQL software appeared in the early 21st century: MongoDB (2009), Redis (2009), Cassandra (2008), etc. Today there is a wide variety of data models used in NoSQL systems. The most popular are shown in Fig. 2:

- Key-value: here, information is stored in records of the “key-value” type and complex data structures, including XML, can be stored as “value”. The search is performed via a key. Dynamo, Riak, Azure, Redis, Cache are such NoSQL databases;
- Document: the work data and related information are stored in documents, most often in the XML or JSON formats. This model resembles the key-value model, with the “value” being the document itself. Such models are MongoDB, CouchDB, Raven, BaseX, etc.;
- Wide column stores: again, a "key" is used, but this may point to a family of columns. Each record can have a different number of columns and can be placed in other columns called super columns. BigTable, Hbase, Cassandra, Accumulo are popular examples of column family database software;
- Graph: this works with graph structures. Data is modeled as a network of links between particular elements. Neo4J, Allegro, Virtuoso, Bigdata are such models;
- Multidimensional: Globals, SciDB, Minim DB.

Among the main advantages of NoSQL databases are:

- flexibility - they do not work with static schemes;
- scalability - they also allow for horizontal scaling;
- facilitated database transfer across multiple servers.

The biggest drawback to NoSQL systems is that they are not transitive.

Typically, NoSQL databases are used in distributed systems information systems, where the emphasis is on productivity in processing large volumes of data, which makes them applicable to information systems in the mining industry.

In such systems, the CAP theorem (Brewer's theorem) is observed [3]: “In a distributed system, at most two of the categories can be satisfied:

- Consistency (C): all database clients see the same information, even with competitive updates;
- Availability (A): all database clients can access any version of the information;
- Partition tolerance (P): The database can be partitioned over multiple servers.

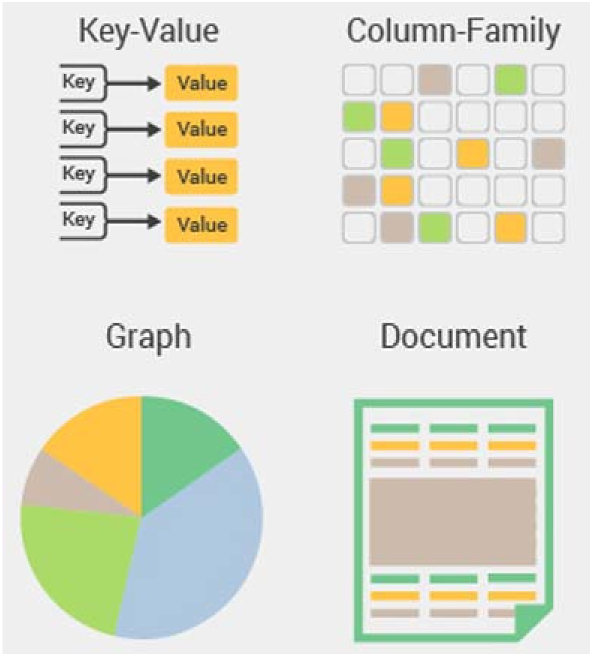

Fig. 2. Popular NoSQL models of data.

The simultaneous provision of all three guarantees is impossible (Figure 3).

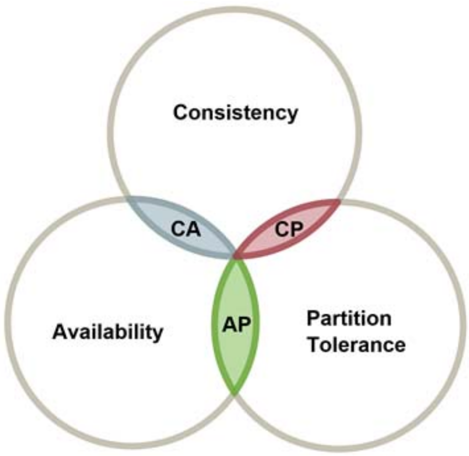

Fig. 3. CAP theorem.

The theorem proves that only two of the three pillars can be used to create such a system, i.e. we may have a system with high consistency and expandability, a system with high data availability and expandability, or a system with high consistency and high availability, but without expandability.

Most NoSQL databases operate on the BASE (Basically Available, Soft-state, Eventual consistency) principle: choosing availability and partitioning at the expense of consistency and looking for the fastest and most reliable synchronization among individual servers.

NoSQL databases still have limited application in specific areas, but the fact that they are used by IT giants like Google, Facebook, Amazon, and LinkedIn is a proof about their potential.

Numerous comparative analyzes of the performance of RDBMS and NoSQL have shown that, in general, NoSQL systems perform better when recording, deleting, and updating Big Data sets than are common to information systems used to manage mining processes.

NewSQL databases have been talked about for the last few years. The term NewSQL was first proposed by Aslett [4]. These are actually databases that combine the advantages of SQL and NoSQL databases (Fig. 3), as NewSQL are transitive and horizontally and vertically extensible.

Fig. 4. Comparison between SQL, NoSQL, and NewSQL.

The products described as NewSQL databases are very diverse, but three main types can be classified:

- SQL engines: highly optimized storage engines for SQL (examples MySQL Cluster, Infobright, TokuDB);
- New architectures: databases that were designed to operate in a distributed cluster (examples Google Spanner, Clustrix, VoltDB, MemSQL);
- Transparent sharding: they provide a sharding middleware layer to automatically split databases across multiple nodes (ScaleBase).

The coal of NewSQL databases is to provide a high-performance and affordable solution for processing large volumes of data without compromising data consistency and high-speed transaction capabilities, making them very efficient and applicable to some processes in the mining industry, which are almost completely automated.

They are best used in the control of enrichment processes, where the data are very high frequency - the sensors (express analyzers) continuously provide information at intervals of up to 2 minutes, which requires the supply of appropriate reagents to obtain the desired content of ore concentrate.

Although in recent years many analytical comparisons have been made between SQL and NoSQL databases [5, 6], today the choice of which data model to use is determined mainly by the specific conditions and tasks.

Data quality assurance technologies

Data quality is a characteristic that shows the extent to which they are analyzed and meet the needs of the business to make informed and effective decisions. From an information technology perspective, data quality is part of the whole data management process.

The criteria determining whether we operate with quality data can be considered according to the requirements of information systems and from the point of view of their users.

The requirement for the use of high quality data in information systems is that they meet at least five main criteria [7] - completeness, accuracy, validity, consistency and timeliness (figure 5).

Unlike standard data collection (on paper), information technologies make it possible to ensure the completeness of data by using functions that allow the input and digital storage of information only, where all attributes for the object, activity etc. have been introduced.

To ensure full quality data, additional features are introduced that check not only the correctness of the data provided but also the exact implementation of the data entry format defined by the particular information system.

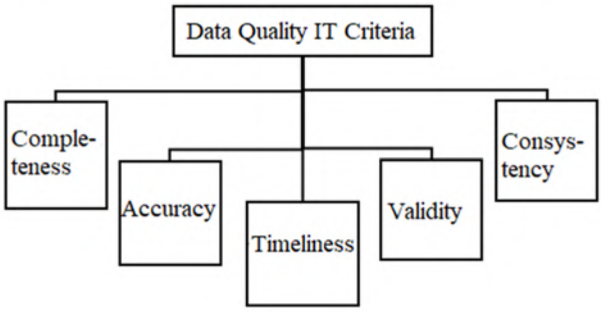

Fig. 5. Main criteria for data quality.

Accuracy of data criterion suggests that incoming data in the information system are correct and fully reflect the depicted object, process, etc. To avoid the risk of inaccurate data submission, the interference of the human factor in this activity should be minimised already at the design stage of a specific information system. Unfortunately, this is almost impossible, and therefore, the implementation of this activity must be done by competent and well trained specialists.

To ensure the data accuracy, especially in cases of a high volume or a continuous stream of data, additional features are being set in the information systems which check for inaccuracies at every step and eliminate admission of such.

The criterion validity of the data determines how data values are correctly measured according to the pre-set conditions. If we have received invalid data, this means that there is a problem in the process of collecting the data.

When you get values for specific data that are beyond the limits of the usual, it does not always mean that they are invalid. In such a case the values should be re-checked. In the flexible information systems this problem is easily solved by altering the defined limits for measured values and incorporating new values.

In information systems, especially in those with longer term of use, there are data about the same object, process, action, etc., that are introduced at certain periods and have different values. In other words, there are different versions of the data for an object or process.

The consistency criterion ensures that the data in the various versions are saved in the same format and in the most important this data format is not changed during processing.

In order for an adequate and efficient decision to be made, it is important that the data we need to analyse should be timely - i.e. there is no time interruption of the incoming data stream for various reasons.

The timeliness criterion is especially important in industrial systems, which manage continuous production processes because the lack of data for a specific segment of time can lead to incorrect management decisions.

From the point of view of data users, the criteria for data quality can be considered conditionally in four major groups - availability, usability, comprehensibility and security (figure 6).

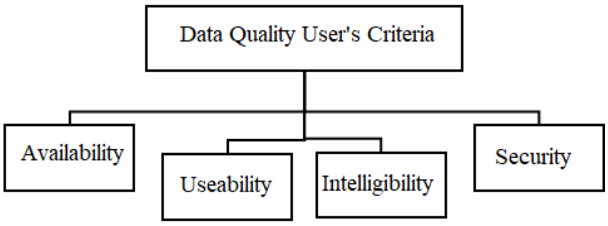

Fig. 6. Users' criteria for data quality.

Availability of data means that in every moment, when appropriate, users need, to have access to them and they are always available.

In information systems, basic characteristics about the availability of data are accessibility, authentication, authorisation, and timeliness of equivalence.

In the client-server technology used by modern information systems by design levels of access to a specific collection of data are defined and an access level is assigned to every particular user, which determines what kind of data to be submitted. Various collections (databases) available for specific levels may exist. An example in this respect are geographical information systems [8], where there is different accuracy (data quality) depending on the type and level of access.

Depending on the specific level of access, it is verified if that user has permission (authentication) to use the information resource (i.e. to a lower or higher quality data). Authorisation is performed by the information system itself, as it gives the user rights to perform the permitted set of actions.

Since a large part of the information systems, including industrial ones, are used by many users, and different users can enter information, the equivalence of data is of particular importance. It measures the extent to which equality (equal values) of the same data is guaranteed.

The timeliness guarantees users that data are timely (as timely as possible), which is essential in making effective decisions.

The usability criterion means that data incoming in the information system from different sources can be processed and analysed.

The data characteristics that determine their usability are documentation, validity, applicability, precision, flexibility and interactivity.

The most important feature of usability of incoming data is their ability to be converted into a digital format by the information system, i.e. they can be formalised by meeting their set conservation model [9].

The validity of the data is determined by comparing the relevance to the requirements set for the specific information system.

Applicability is a characteristic that determines how much data can be processed and analysed in support of specific targets. In order to have adequate solutions taken on the basis of the data it is necessary to have precise data – i.e. they need to have values in the range specified in the information system. Thus, the level of detail of the data, which is required by different groups of users and management levels, is defined. The too high level of refinement and detail of data often leads to difficulties in the operation of information systems and it is therefore necessary to find a level of balance that satisfies both these two characteristics.

Data security assures the users that they are provided with the requested information in an accessible form and the data origin is guaranteed.

The main features ensuring data security are standardisation, reliability, comprehensiveness, integrity, objectivity, comparability and stability.

Standardisation ensures that the data submitted and processed correspond to the rules set in each information system, which in some cases are valid for different information systems that share and exchange information. This data feature is set in the design process of the relevant information system and is monitored throughout its entire life cycle.

Nowadays, the reliability of data is a key feature not only for information systems but also for society as a whole. They give confidence about the source of the data and its reputation, which determines the degree of confidence in the data. Comprehensiveness is a complementary feature that determines to what extent the data is satisfactory and covers the user's request. Data integrity is one of the most important features of data, especially in an insecure environment such as the Internet, because it ensures that changes to data are made only by authorised users. The objectivity feature of the data ensures that the data are not modified under the influence of human emotions, i.e. only the specific facts about the data are reflected.

Naturally, one of the most important features of data is the ability to be permanently stored and accessible over a long period of time to ensure its stability.

Information technology uses many different techniques that guarantee the use of only high quality data. As particularly critical in this regard we can identify technologies that provide standardization, profiling, matching, control and cleaning of real-time data (Fig. 7), which are particularly important in ensuring the operation of information systems in the mining industry.

Data standardization is a technology that operates on the basis of established rules and criteria, ensuring the desired quality. The received data goes through various transformation processes in order to comply with the rules set in the specific information system. [10] Additional functions must be included, allowing automatic correction in the presence of minimal inaccuracies or rejection of data in case of significant discrepancies.

Data standardization is especially important in ERP systems, where information comes from different sources. This technology is also essential when we have data exchange between different information systems with diverse databases, such as those used in the management of various processes in the mining industry.

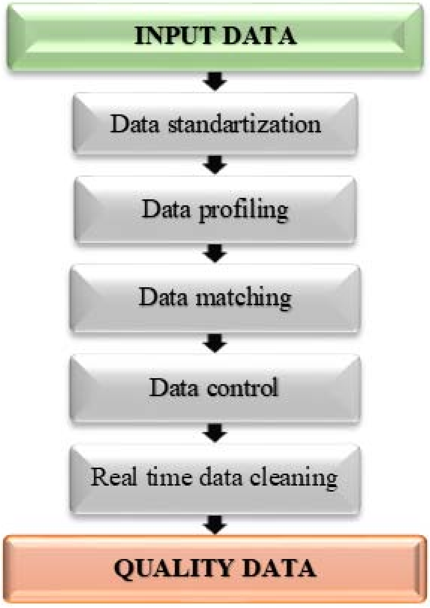

Fig. 7. Data quality assurance technologies.

Data profiling is a technology used to analyses the content, quality, and structure of output data, and is used in various criteria for data quality, such as determining their accuracy and completeness.

Data sources are considered, with an initial assessment of the data to identify potential and actual deficiencies. The goal is to find out the wrong areas in the data organization that can be found in user input, interface errors, data corruption when transferring, and so on. The use of this technique significantly improves data quality.

Data matching aims to find records that relate to the same object, process, individual, and so on. It can be done in many different ways, but the process is often based on algorithms or programmed circuits, where processors perform sequential analyzes of each individual data set, comparing it to each individual part of another data set or comparing complex variables for finding strings containing specific similarities. In the paper of I. Getova [11] present innovative test and evaluation model which gives a probability assessment obtained learning of the lectured material by the learners and provides information on how much the learner perceives the new material and how well the lecturer has presented it in a way can be readily understand it of students. The analysis in this article is performed on a set of data collected by two universities in Bulgaria using the IBM statistical analysis program - SPSS.

Data control is a set of technologies that monitor changes in data quality over time and report deviations from predefined quality indicators. The control of the data is realized through various software tools (drop-down menu, mandatory field, etc.), which monitor and guarantee the completeness, accuracy, validity, timeliness and other quality characteristics of the submitted data.

The timeliness of data in information technology is most easily ensured through cloud structures where all data about a particular object, process, individual, automatically transferred to the cloud once a process is complete and immediately available to all users authorized to work with them.

The data cleaning process monitors for incorrect, incomplete or inaccurate data and ensures that all obsolete or non-compliant data quality criteria are removed.

In modern information systems, software tools for quality control and data cleaning are built into the respective input modules, which allows them to work in real time. In this way, incomplete, inaccurate and outdated data are not allowed to enter, which maximally supports the making of the right management decisions.

This is the process that ensures that the data is correct, consistent and applicable. Data clearing is important because it improves data quality by removing any obsolete or incorrect data and leaving the highest quality information.

For the data to be used by different management levels (different user groups) and to be available on different devices (PC, Tablet, Smartphone), it is necessary to possess flexibility, which is particularly important in ERP systems in the mining industry. This means that they are subject to processes for different organizational changes or reengineering with minimal modification of the existing objects and relations in them. The use of information systems through the Internet or in a network mode requires the data to be interactive – that is, to have two-way communication between the data and users.

Conclusion

Although relational databases are still widely used in the mining industry, with the increasing volume of processed data distributed in the Web environment and the introduction of the Internet of Things, they are finding it increasingly difficult to handle large real-time data sets. NewSQL databases still offer partial solutions, but NoSQL has already established itself in certain areas as a better solution than classic RDBMS.

The information systems used in the mining industry are characterized by their specificity and diversity both for the type of mineral deposit (each deposit is unique) and compliance with the requirements of the specific company [9, 12, 13], which is a prerequisite for the integration of NoSQL data models in it due to their flexibility.

More and more mining companies plan, manage and control their activities, using specialized information systems adapted to their conditions and requirements. Since many large mining companies, incl. and in Bulgaria they are already building their own cloud structures, using information from different types and models of databases, the technologies guaranteeing the processing of high quality data are of special importance.

However, due to the diversity of the software tools used, the implementation of all criteria for high quality data proves to be a difficult problem to implement, as an optimal balance between all criteria is sought.

For this reason, each mining company, depending on its requirements and available software tools, determines which quality criteria are most important for its work at a particular time, and this process is dynamic with the introduction of new information technologies.

Abstract. When mining ore bodies in Kryvyi Rih iron ore basin, underground mines apply open stoping or bulk caving systems in proportion of 55% to 45%. Most of underground mines prefer stoping with pillar caving. Yet, rock pressure contributes to growth of costs for workings maintenance and deterioration of extraction indices. Rock mass extraction indices can be enhanced by application of a protectve structure in the upper part of the block that will enable additional decrease in load on the draw level. There are a great many of methods for determining parameters of constructive elements of the protective structure that help keep its integrity for the whole period of block mining. The article suggests methods for determining parameters of the protective structure when mining steep ore bodies. The research conducted demonstrates that with the inclined protective structure, increase of unit load on it from 200 to 1200t/m^2 leads to decrease of its thickness from 6.3-20.9m to 5.5-18.4m and increase of the crown length from 40m to 60m. The developed block caving system with application of the protective structure when mining steep ore bodies enables overall decrease of ore dilution in the block by 3%, increase of iron content in the mined ore by 1.3% without significant mining costs growth and decrease of loads on the workings of the receiving level.

1 Introduction

Ore bodies of Kryvyi Rih iron ore deposit (Ukraine) house over 30.2 Bt of ferruginous quartzite with iron content of 24-65% [1-4]. These ore bodies are mined applying surface and underground methods. Underground methods are used to mine rich iron ores with iron content of 57–65% applying stoping systems and bulk caving of ore and overlying rock in proportion of 55% to 45% [5-8]. Most of underground mines prefer stoping with pillar caving. Yet, in complicated mining and geological conditions rock pressure contributes to growth of workings maintenance costs and deterioration of extraction indices [9-12].

Underground mining operations have reached the depth of 1350 m. Ore bodies stretch for 800-1200 m, their horizontal thickness is 30–120 m and the angle of slope is 45–85 degrees [13-16]. The authors of [17-20] state that ore bodies significantly differ from each other in not only physical and mechanical properties that influence mining and processing technologies but also their quality. Mining of agglomerated iron ores is the main type of activities of enterprises that are engaged in underground mining of naturally rich iron ores. In compliance with specifications, agglomerated ores are produced at grinding-sorting complexes of underground mines through grinding at several stages, screening and blending at surface stockpiles [21-25].

To enhance indicators of the final product, concentration complexes apply various technologies and methods of controlling the process of concentrating crude ore considering energy-efficiency indicators [26-29]. To settle resource saving issues, a modern complex approach of controlling environmental-economic systems applying the theory of administrative-engineering management is used. Yet, this results in increased mining costs and alienation of land for concentration waste storage.

When mining ore bodies in complicated mining and geological conditions, ore losses and dilution become higher by 3-5% as compared with the standards. Increased losses and dilution result in pre-schedule mining-out of the level, increased volumes of capital mining operations and ore mining costs [30-33].

The authors of [33-38] suggest various options of mining ore bodies that enable enhancement of ore mass extraction from stopes. However, rock pressure may lead to stope failures when forming a compensation space and, consequently, result in deterioration of extraction indices, decrease of labour efficiency and increase of time spent on mining a block.

At Kiruna mine, application of the bulk caving system without considerable exposures enables enhancement of ore extraction indices in unfavorable mining and geological conditions [39, 40]. Managers of Kryvyi Rih underground mines have made several attempts to implement the system. However, this has resulted in

* Corresponding author: psvknu@gmail.com

deterioration of labour conditions and increased mining costs due to complicated mining and engineering conditions (instable fractured ore and rocks).

To enhance extraction indices, the sublevel caving system with an artificial flexible metal layer was applied to extract polymetal ores at Bakyrchik mine (Kazakhstan). The developed option with a flexible metal layer in the upper part of the block and longhole blasting (Fig. 1) has proved to be efficient despite considerable economic indices of mining [41-43].

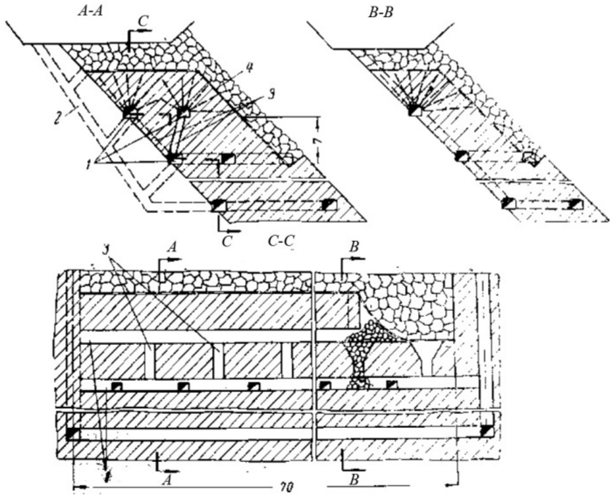

Fig. 1. Ore mining under a flexible layer: 1 – drill sublevel drifts; 2 – orepass; 3 – box raises; 4 – the flexible layer.

It should be noted that application of this mining system requires that flexible roofing should be sufficiently strong and withstand not only static but also dynamic loads when stoping. It has proved to be not only protecting against caved rock coming into the face space but also a load bearing support that creates safe working conditions.

The state research ore mining institute "SkhidNDGRI" has suggested the option for mining blind ore bodies with drawing the broken ore under the protective rock block-shield that separates caved rock and ore [44] (Fig. 2).

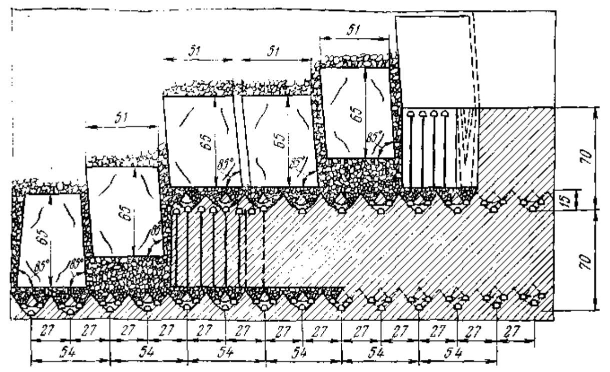

Fig. 2. The system of induced block caving under the protective rock block-shield.

Kuznetsk metallurgical plant (Russia) has tested this technology at its mine. The experimental block was formed in the 10-20 m thick magnetite ore body with sulphide inclusions at the depth of 130-150 m. The stope was mined applying block caving with layered ore breaking by a bunch of parallel contiguous boreholes on the "compressed environment". The caved ore under the rock block-shield was drawn applying scraper equipment.

Geometry of the stope was as follows: length – 36 m; width – 16-20 m; height of the caved ore layer – 32.5 m; length of the block-shield – 30 m, distance between block-shields – 2.5-3 m. Ore massif was broken by 10-13 m wide parts bunches of parallel contiguous boreholes. The ore was drawn successively from drawpoints until the block-shield moved vertically for 13 m. Then the ore was drawn from the previously broken adjacent block. Application of this technology enabled high ore extraction indices [44].

Thus, the technology of mining blind ore bodies applying a block-shield is rather promising. Yet, its application is possible for steep ore bodies only.

The sublevel caving system with creation of rock and ore moving protective structure (the "floating" crown) is suggested to mine parallel contiguous steep ore bodies [45] (Fig. 3).

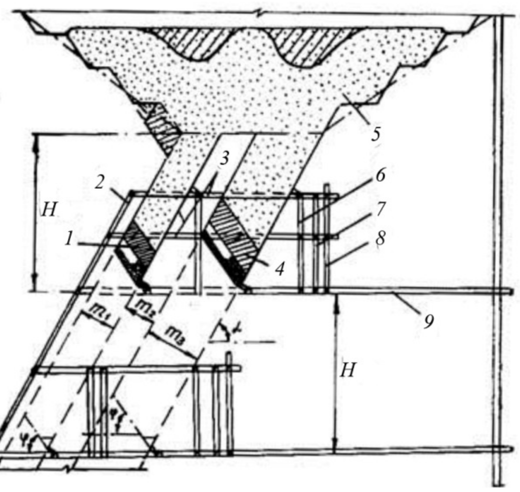

Fig.3. The flowsheet of forming "floating" rock and ore crowns (FC): 1, 4 – rock and ore FC; 2, 6, 7, 8 – ventilation, ore drawing, manway and service raises respectively; 3 – drilling sublevels; 5 – overburden rocks of the inside dump; 9 – the haulage level.

In this case, in the upper part of the stope, the FC is formed at a certain angle (Fig.3). To control vertical movements of the FC, a remote control circuit is developed. The authors suggest determining the FC thickness applying methods for defining structural elements of the room-and-pillar system for the inclined crown. Permissible dimensions of exposures and pillars are calculated depending on the level height and the FC thickness on the basis of methods developed by the research ore mining institute.

The FC is formed by drilling and blasting. Along the strike, the crown is formed from drill drifts of the footwall and the hanging wall with the help of short holes; across the strike – from a drill drift by longhole rings.

Ore stoping is performed until the FC is formed. For this, a drawing level is formed in the stope by a cut raise and the ore massif is caved by blasthole rings. After the mining block is filled with the broken ore, the FC is formed and the broken ore is drawn off from the stope

https://doi.org/10.1051/e3sconf/202128008013

under the crown, vertical movement of the crown being controlled.

To provide even movement of the FC, caved ore should be controlled, especially while drawing from a series of drawpoints. For this, it is necessary to create a single drawing zone (one drawing crater 7 and a loosening zone 2, 8) in the center of the block (panel) as when drawing from a single drawpoint (Fig. 3).

Even vertical movement of the FC with its integrity preserved for the whole period of mining depends on the following factors: physical and mechanical properties of ore, the draw level parameters, overlying rock pressure on the FC.

According to [46-49], uniform sequential drawing of caved ore from adjacent drawpoints shifts the centers of both drawing figures and results in intensive formation of one drawing figure out of two [49] (Fig. 4).

In [48], the author states that in case of non-observance of the uniform advanced mode of drawing, there may be formed two or even three and more craters under the FC. This will result in significant losses and dilution due to the craters running beyond the protective structure, and in more complicated control over the even FC movement

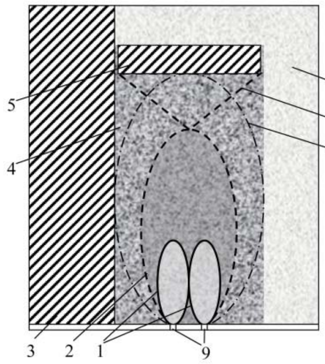

Fig. 4. Formation of drawing and loosening figures and a draw crater while drawing caved ore from a series of drawpoints: 1 – the drawing ellipsoid; 2 – the loosening ellipsoid; 3 – uncaved massif; 4 – caved ore; 5 – the FC; 6 – caved rocks; 7 – the draw crater; 8 – the loosening ellipsoid at the moment of reaching the FC; 9 – drawpoints.

To prevent the draw crater running beyond the FC, construction of the protective structure should be changed (Fig. 5). Thus, creation of the FC with protective brows in the lower part along its perimeter enables decreasing side dilution of the caved ore. Parameter of the protective brow are determined based on conditions of its formation (by drilling and blasting), compressive strength and the number of FC. The height of the protective brow (h_{br}) makes 3-5 m and it is determined by parameters of the drilling room.

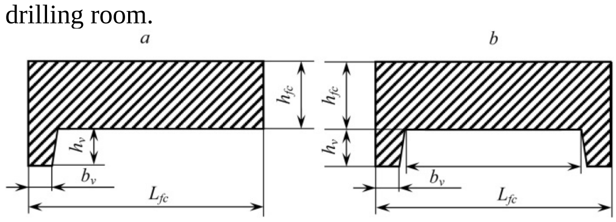

Fig. 5. The principle diagram of “floating crowns”: a – asymmetric “Г”-shaped; b – symmetric “П” – shaped.

Thus, enhanced extraction indices can be achieved through separation of broken ore and caved rock by the protective structure [36, 39, 43].

2 Methods

Application of the protective structure in the upper part of the block enables redistributing of loads on the draw level and enhancing indices of caved ore extraction from the stope. However, there is no technology for mining steep ore bodies by bulk caving and applying the protective structure. Thus, research into and enhancement of the technology of stoping under high rock pressure remains actual.

The work aims to enhance the technology of mining steep ore bodies applying the moving protective structure in the upper part of the stope.

The task of the work consists in developing the technology able to provide increased iron content in mined ore mass in complicated mining and geological conditions.

3 Results and discussion

In underground mining, calculation of pillars between underground rooms and the open stoping space is of great interest. These pillars can be treated as crowns.

The widely used method of calculating the crown thickness is based on the rock fragmentation factor at caving. This method is used for low stopes. If stopes are high, thickness of crowns would be inexpediently great. There are a number of constraints considering which safe dimensions of crowns should be calculated on the basis of cave arch parameters. Height of the natural arch is known to depend on the working width and physical and mechanical properties of rocks. Despite all advantages of this method of calculating the safe FC thickness, it is insufficiently reliable due to the fact that in conditions of large roof exposures, determination of cave arch parameters is rather difficult [44]. At that, it is practically impossible to determine the moment when formation of the dome of equilibrium is finished.

To calculate the safe thickness of a crown, the most reasonable are the methods of structural mechanics that are described in recent scientific works [5, 6, 44-46]. The authors of the works recommend to distinguish among three types of crowns: *a* – a long thick beam-like plate constrained along the contour; *b* – a plate constrained along the contour and with fixed corners if its length-to-width ratio equals or exceeds six; *c* – a plate constrained along the contour and with fixed corners if its length-to-width ratio is less than six.

Crowns of various types can be calculated with insignificant errors using a unified methodology, this facilitating such calculations in production conditions. As mentioned above, the FC thickness depends on the exposure span, physical and mechanical properties and rock loads. Along with that, it should be taken into account that unreasoned increase of the FC thickness in order to raise the factor of safety leads to increased losses of the useful mineral.

The FC is treated as a separately structured plate-like part of the massif moving together with overlying rocks. According to the above mentioned, the width and the length of the FC are equal, so let us treat it as a plate resting on a moving support ("support pillars") consisted of the caved ore and located near a draw crater. The FC undergoes loads from its weight and the weight of the caved rock [44, 45]. Bending moments in section points of the crown are calculated similarly to those for a plate freely abutting with its four sides. Stresses impacting the plate along the x-x and y-y axes are calculated by the expression

$$\sigma_x = \sigma_y = \frac{12M_{x\,max}}{h_{fc}^3} z = \frac{12M_{y\,max}}{h_{fc}^3} z\,, \qquad (1)$$

where $M_{x\,max}$, $M_{y\,max}$ are values of the maximum bending moment in the z part of the span of the "floating crown" exposure along the x and y axes respectively; h_{fc} is the thickness of the "floating crown", m; z is the distance on which the largest stresses occur in the plate, m.

According to [50]. The largest stresses occur at $z = \pm h/2$. Thai is why, stresses in the plate under load should satisfy the condition

$$\sigma_{x\,max} = \sigma_{y\,max} = \frac{6M_{x\,max}}{h_{fc}^2} = \frac{6M_{y\,max}}{h_{fc}^2} \le \left[\sigma_p\right], \qquad (2)$$

where $[\sigma_p]$ is the permissible tensile stress of rocks making the "floating crown", t/m^2.

As the FC length and width are equal, expression (2) will look like

$$\sigma_{max} = \frac{6M_{max}}{h_{fc}^2} \le \left[\sigma_p\right], \qquad (3)$$

where M_{max} is the total of bending moments in the middle part of the FC exposure span.

The value $[\sigma_p]$ in expression (3) is calculated as follows

$$\left[\sigma_p\right] = \frac{K_f\, f_p K_o}{K_z}\,, \qquad (4)$$

where K_f is the coefficient of converting rock hardness into stress; f_p is the Protodyakonov hardness ratio of rock including those of the "floating" crown; K_o is the factor of rock loosening caused by fissures (assumed from 0.5 to 0.85); K_z is the safety factor of rocks of the "floating" crown (changing from 1.5 to 2.5).

When mining steep ore bodies, [45] suggests forming the FC not horizontally but at some angle to the receiving level.

The crown should be inclined at the angle that will not allow its turning over in the stope from the hanging wall side, i.e. the angle between the stationary crown and the hanging wall does not exceed 80 degrees (Fig. 6).

The minimal crown inclination angle α_{fc} for steep ore bodies is generalized by the expression, degrees

$$\alpha_{fc} = 100 - \alpha_w\,, \qquad (5)$$

where α_w is the dip of the hanging wall rocks, degrees.

Formula (5) is true when the ore body dip changes from 40 to 80 degrees. Considering the fact that the FC is inclined, stress components will be redistributed according to the expression

$$\left[\sigma_p\right] \sin\alpha_{fc} = \frac{K_f\, f_p K_o}{K_z}\,. \qquad (6)$$

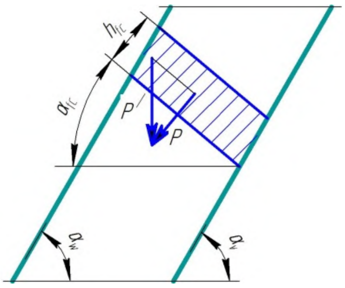

Fig. 6. The principle diagram of determining the FC formation angle.

Solving the equation (3) with respect to h_{fc}, we will obtain the general expression for determining the maximum permissible thickness of the "floating" crown

$$h_{fc} = \sqrt{\frac{6M_{max} K_z \sin\alpha_{fc}}{K_f\, f_p K_o}}\,. \qquad (7)$$

Taking into account independences of force actions, the value of the maximum bending moment is calculated as the total of moments of each load according to the expression

$$M_{max} = M_{max}^c + M_{max}^p\,, \qquad (8)$$

where M_{max}^c и M_{max}^p are values of the maximum bending moments on the span of the "floating" crown exposure depending on the weight of the crown itself and the weight of overlying rocks respectively.

The bending moment from the "floating" crown weight is determined as follows

$$M_{max}^c = \beta_m P_{cr} l_{sp}^2 \gamma_o\,, \qquad (9)$$

where β_m is the bending moment in the freely abutting plate ("floating" crown) equaling 0.0479 [50]; P_{cr} is the load caused by the weight of the crown on 1 m of its width, t/m^2; l_{sp} is the span of the exposure under the "floating" crown, m; γ_o is the volumetric weight of the crown rock, t/m^3.

Let us consider the FC lying on the caved ore as a plate [50]. The bending moment caused by the caved rock weight impacting the "floating" crown four sides of which rest on support pillars is described by the differential equation

$$\frac{\partial^4\omega}{\partial x^4} + 2\frac{\partial^4\omega}{\partial x^2 \partial y^2} + \frac{\partial^4\omega}{\partial y^4} = 0\,. \qquad (10)$$

Task (10) is solved considering boundary conditions. If the crown abuts freely with its four sides is freely supported, the boundary conditions will look like (11), and the task is solved by numerical methods

$$\begin{cases} \omega\big|_{x=0}^{x=a} = 0, \\ \left.\dfrac{\partial^2\omega}{\partial x^2}\right|_{x=0}^{x=a} = 0, \end{cases} \text{и} \begin{cases} \omega\big|_{y=0}^{y=a} = 0, \\ \left.\dfrac{\partial^2\omega}{\partial y^2}\right|_{y=0}^{y=a} = 0, \end{cases} \qquad (11)$$

 https://doi.org/10.1051/e3sconf/202128008013

where a is the FC length (width), m.

As solution of equation (11) requires use of numerical methods which are cumbersome, the author of [50] suggests a simplified equation to determine the maximum bending moment in engineering calculations

$$M_{max}^{p} = C_1 P_{cr} l_{sp}^2 , \tag{12}$$

where C_1 is the adjustment coefficient of bending moments, [50]; P_{cr} is the load of overlying rocks on 1 m of the FC width, t/m^2.

Substituting the value of the bending moment calculated by formula (12) in expression (7), we obtain the final expression for determining the minimal permissive thickness of the FC

$$h_{fc} = 0{,}1437 l_{sp} \sqrt{\sin\alpha_{fc}} \left(\frac{l_{sp}\gamma_o K_z}{K_f f_p K_o} + \frac{\sqrt{\left(l_{sp}\gamma_o K_z\right)^2 + 290{,}65 C_1 P_{cr} K_f f_p K_o K_z}}{K_f f_p K_o} \right). \tag{13}$$

Vertical movement of the FC occurs during caved ore drawing due to destruction of the support pillar which the crown rests on. Let us assume that at the angle of the support pillar rocks shear, the shearing and holding forces are in bounding equilibrium. So, stability of bounding equilibrium is described by Coulomb's law and looks like

$$\tau = \tau_o + \sigma_n \, tg\rho , \tag{14}$$

where τ is the shearing stress in the support pillar, t/m^2; τ_o is the initial shear resistance which equals rock cohesion c at $\sigma = 0$, t/m^2; σ_n is the normal stress in the support pillar, t/m^2; ρ is the friction angle, degrees.

Normal and shear stresses are included in equation (14) and determined as follows

$$\sigma_n = \sigma \cos\theta , \tau = \sigma \sin\theta , \tag{15}$$

where σ is the effective value of the compacting stress, t/m^2.

The compacting stress σ is the ratio of the total weight of overlying rocks (P_{rock}) and the "floating" crown (P_{cr}) to the total area of the "support" pillar cross section (S_{max}) [51-54]

$$\sigma = \frac{P_{rock} + P_{cr}}{S_{max}} = \frac{P}{S_{max}} , \tag{16}$$

where P_{rock}, P_{cr} are loads caused by overlying rocks the FC respectively, t; S_{max} is the area of the cross section which the FC rests on, m^2.

On solving (16) with regard to S_{max}, we obtain the formula for determining minimal permissible areas of the "support" pillar that bears the FC

$$S_{\text{г}p} = \frac{P\left(\sin\theta - \cos\theta \, tg\rho\right)}{c} . \tag{17}$$

Then, when drawing ore from a series of drawpoints, the maximal exposure span under the "floating" crown is calculated by the formula

$$l_{sp} = 2\sqrt{\frac{ca^2 - P\left(\sin\theta - tg\rho\right)}{\pi \, c}} . \tag{18}$$

The research conducted enables the conclusion that the exposure under the FC depends on physical and mechanical properties of ore and the effective load P that consists of the weight of the overlying rocks and the weight of the "floating" crown. In its turn, the weight of the "floating" crown depends on its constructive parameters (width, length and thickness).

Based on calculations of the crown thickness considering the FC inclination angle, the dependencies of the "floating" crown thickness on the unit load on the FC at the ore body dip of 60° are built (Fig. 7).

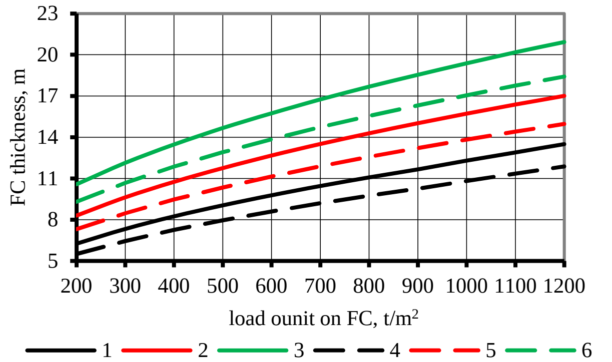

Fig. 7. Dependency of the "floating" crown on the unit load on the protective structure and its parameters at: 1, 2, 3 – the FC lengths of 40 50 and 60 m respectively at the angle of 0°; 4, 5, 6 – the FC lengths of 40, 50 and 60 m respectively at the angle of 40° to the receiving level.

Fig. 7 demonstrates, that if the unit load on the FC increases from з 200 to 1200 t/m^2 and the crown incline angle of 0° and 40°, the crown thickness grows from 6.3 to 20.9 m and to 5.5 to 18.4 m respectively. It should be noted that the character of crown thickness changes at the angles of 0° and 40° is similar. Thus, it can be concluded that calculations based on the enhanced methods provide reliable results.

The conducted research enables the conclusion that depending on the location of drawpoints, waste rock can get into the mining block. This happens when the caved ore is drawn under the FC inclined against the receiving level. (Fig. 8).

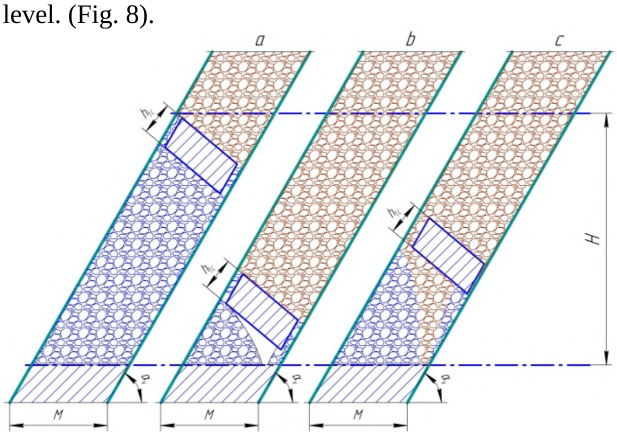

Fig. 8. Diagrams of the FC movements while ore drawing: *a* – the initial stage; *b* – the final stage of caved ore drawing; *c* – the final stage of caved ore drawing after the active drawing area moves beyond the protective structure.

Yu.P. Kaplenko and V.O. Kolosov state that after ore drawing from the stope, the FC will move as shown in Fig. 6*b*. However, according to S.V. Pysmennyi's research, the drawing area moves beyond the FC with the 50% probability and lets waste rock into the active drawing zone (Fig. 8*c*). To prevent this, it is suggested to create protective brows in the lower part of the crown (see Fig. 5).

Analysis of caved ore drawing under the protective structure when mining steep ore bodies enables the conclusion that it is reasonable to locate protective brows in the upper part of the FC from the hanging wall side (Fig. 9).

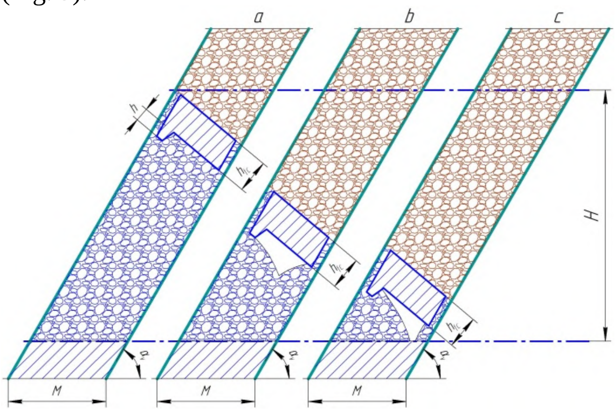

Fig. 9. The diagram of movement of the FC with a protective brow from the hanging wall side when drawing caved ore: *a* – the initial stage; *b* – the intermediate stage; c – the final stage.

Fig. 10 demonstrates that when forming a draw crater under the FC (the intermediate stage), the protective brow does not allow it to go beyond the protective structure that prevents waste rock from coming to the active drawing area.

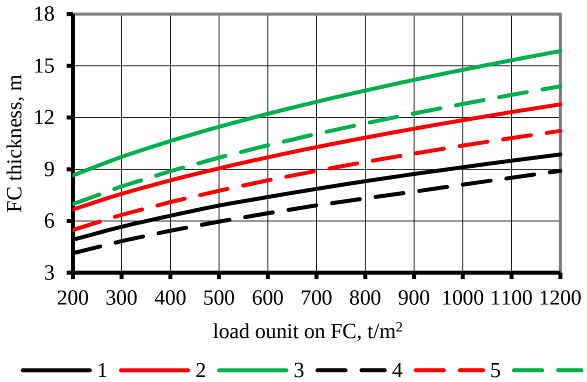

Fig. 10. Dependency of the “floating” crown with the protective brow on the unit load on the protective structure and its parameters at: 1, 2, 3 – the FC lengths of 40, 50 and 60 m respectively at the angle of 0°; 4, 5, 6 is the FC lengths of 40, 50 and 60 m respectively at the angle of 40° to the receiving level.

As is seen in Fig. 10, if the unit load on the FC increases from з 200 to 1200 t/m^2 and the crown incline makes 0° and 40°, the crown thickness grows from 4.9 to 15.9 m to 4.1 to 13.8 m respectively. It should be noted that the character of crown thickness changes at the angles of 0° and 40° are similar. Thus, it can be concluded that calculations based on the enhanced methods provide reliable results.

Analysis of calculations in Fig.7 and 10 shows that it is possible to decrease the crown thickness applying the protecting brow in the upper part of the FC. It should be noted that the crown thickness decrease leads to increase in general reserves in the FC at the expense of ore reserves in the protecting brow.

To reduce dilution of the caved ore and decrease rock pressure manifestations, we suggest a system with bulk caving of ore and overlying rocks applying the “floating” crown (Fig. 11).

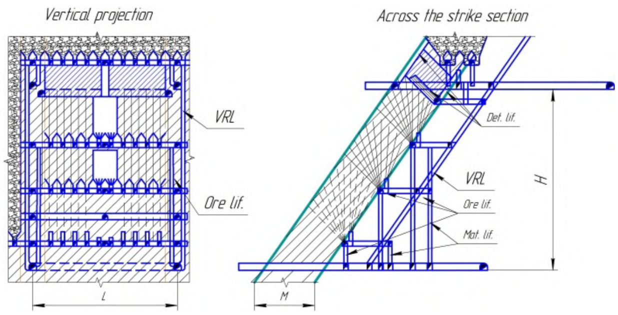

Fig. 11. The system of induced block caving with breaking ore on the vertical compensation room and applying the “Г”-shaped “floating” crown.

The suggested mining system consists in the following. In the upper part of a stope a FC is formed by breaking ore massif along its contour. The stope is conditionally divided into two or three levels where a scraper entry is located from which ore massif is broken on the vertical compensation room.

Geometry of the mining system is as follows: the level height is 10 m, the block length is 60 m, thickness is 25 m, the FC thickness is 15 m according to the calculations (Fig.10). Preparation of the block starts with driving access orts from the haulage entry and driving ventilation and manway raises on the flanks of the mining block. Then the level is conditionally divided into 25 m long sublevels; from ventilation and manway raises, ventilation and manway orts are driven to which service and ore discharge raises are driven up from the haulage level. A scraper entry is driven from the ventilation and manway orts in the footwall. 5-7 m high drawpoints go out of the scraper entry [55-58].

A 15 m thick FC is formed in the upper part of the stope. The FC is cut by driving horizontal and vertical cutoffs. To prevent the active drawing zone from going beyond the FC, the “Г”-shaped protective structure is suggested.

The ore massif of the main reserve is caved after creating the FC. For this, the ore massif is broken by blasthole rings. from the scraper entry on the previously created compensation room. After that, the blasthole rings are fired with delay.

Caved ore drawing begins at drawpoints located in the block center (according to Yu.P. Kaplenko) to create a single active drawing zone (according to S.V. Pysmennyi) until the fragmentation ellipsoid reaches the FC (this makes about 15-20% of the main block reserve). After the fragmentation ellipsoid reaches the FC in the ore massif, the fragmentation factor will be over 1.5. This will enable the FC to move vertically due to its own weight and the weight of the overlying rocks. After the FC movement, the fragmentation factor in the block will decrease to 1.3 and this will stop movement of the protective structure.

With further ore drawing, the factor changes to 1.5, this resulting in the FC movement.

As ore breaking is performed by stages, a pillar is left above workings of the receiving level. The pillar absorbs loads from the broken ore, the crown and caved rocks, thus limiting conditions of rock pressure manifestations in workings. After extracting 50% of ore mass, the lover part of the ore massif is drilled out and ore drawing continues [59-61].

General technical and economic data is given in Table 1.

Table 1. Technical and economic data by mining systems.

Parameters	Mining system	
	Traditional	**Suggested**
Balance ore reserve in block, t	420746	420746
Ore mass mined from block, t	401621	388577
Specific consumption for workings, m/kt	4,3	4,4
Per meter run:		
a) while forming compensation space, t	12.9	12.1
b) while bulk caving, t	18.4	18.4
c) with “floating” crown	–	15.2
Blasting ratio: kg/t		
a) packaged explosives	1.35	1.52
b) granular explosives	0.267	0.294
Labor efficiency, t/shift:		
a) at breaking	1052	898
b) at transportation	509	542
c) by mining system	52.1	50.9
Fe content, %:		
a) in massif	62.0	62.0
b) in ore mass mined	58.63	59.63
Ore loss, %	16.0	18.8
Ore dilution, %	14.0	9.85
Cost of 1t of ore	11.48	11.14

Table 1 demonstrates that application of the FC mining system results in mining costs reduced by 0.34 USD/t, ore losses increased by 2.8% (FC ore excluded), and ore dilution decreased by 4.15% as compared with traditional mining systems. Iron content in the mined ore increases by 1.0%.

Conclusions

The research conducted enables the following conclusions:

1. Based on the analysis of mining and geological conditions of mining under rock pressure in Kryvyi Rih iron ore basin, enhancement of ore extraction from the stope has been proved possible due to application of the protective structure.

2. The current methods of calculating the “floating” crown thickness enable determining its optimal parameters to ensure its integrity when stoping. However, there are no developed techniques of applying the FC when mining steep ore bodies.

3. The enhanced methods have been developed to determine the FC thickness considering the dip angle of the ore body. Based on the research conducted, there has been developed a system of block caving with application of the “floating” crown to mine steep ore bodies that enables decrease of ore dilution, increase of Fe content in the mined ore without considerable growth of ore costs.

The work was supported by the Ministry of Education and Science of Ukraine within the framework of the state scientific topics “Determination of regularities of the stress-strain state of rocks disturbed by workings with the purpose of developing resource-saving ore mining technologies” (State registration No. 0115U003179).

Abstract. The safety factors for different variants of operation development were obtained, on the basis of which the technical and economic indicators were established and the most expedient way of restoration of dump operations in conditions of the formed landslide was chosen. The solutions were proposed for the external dump No 2 of the Central Ore Mining and Processing Enterprise (COMPE), that allow to continue its future operation. When working in the conditions of the formed landslide, three variants of the further dump operation are modeled: the first one - with landslide removal and unloading of the upper dump horizons, the second one - without landslide removal and involvement of disturbed lands in land allotment, the third one - with the landslide loading. Based on the built sections of the dump and defined physical and mechanical properties, the stability factors were obtained for different options of the operation development, which made it possible to determine the appropriate option to eliminate the effects of the dump slide deformations. As a result of the calculations, the cost flows for each of the proposed options of the formation of the end contour of the dump No 2 are determined.

1 Introduction

Practice and scientific research show that the overburden rocks during the development of deep open mines are stored in external dumps, which occupy large areas. Their systematic expansion and considerable distance from the open mines lead to a significant increase in the cost of field development as a whole. To place the dumps, in some cases, hollows and ravines are used, which are almost impossible to use in agriculture. When storing overburden rocks in such conditions, it should be accounted that the weight of the dump placed in the hollows effect the base and can lead to deformation of the sides. Such processes can be facilitated by the presence of ground and surface water, which moisten the rocks of the dump base. The formation of such deformations, as a rule, occurs outside the land allotment of the enterprise. In this regard, there are unforeseen costs to eliminate the effects of deformation, which in difficult economic conditions and reducing demand for iron ore concentrate is unacceptable.

2 Analysis of studies

The development of deep open mines in Ukraine is accompanied by the placement of overburden rocks in external dumps. Issues of dump formation have been considered in various scientific papers [1-8]. The volume of the overburden rocks extraction of and their storage in the external dump directly depends on the productivity of the open mine where minerals are extracted [9-17]. The placement of overburden rocks and the productivity of open mine equipment is an important task that affects the sequence of dump development and the stability of slopes. Many scientific works consider methods of strengthening berms and ledges and methods of construction of potential sliding surfaces and calculations of strengthening parameters, which is confirmed by considerable experience in strengthening unstable surfaces. Problems of stability of slopes of quarries and dumps were considered in many scientific works [18-21]. Solving the problem of stability makes it possible to increase naturally or artificially the safe operation of external and internal dumps.

3 Problem formulation

The Dump No 2 of the PJSC Central Ore Mining and Processing Enterprise (excavator) is located at a distance of 12 km from the open mine in the Oleksandro-Maryivska hollow (Fig. 1). Loose and rock mass are stored in the dump, which are delivered by rail transport. In fact, the dump is poured in succession in several tiers. At the dump No 2, the overburden rocks is accepted at 2 dump dead ends and is dumped with the help of ECG-8I and EK 10/70 excavators. Overburden rocks in the dump

* Corresponding author: shustov.o.o@nmu.one

No 2 of the PJSC "COMPE" is delivered from the faces and reloading points of the open mine No 3. The transport development system is used in this open mine.

As a result of the landslide that occurred on the dump No2 of the Petrovsky open mine of the PJSC "COMPE", 1.42 hectares of arable land were disturbed. There was a need to take measures to eliminate the effects of the landslide. In this regard, options for further dump operation were considered.

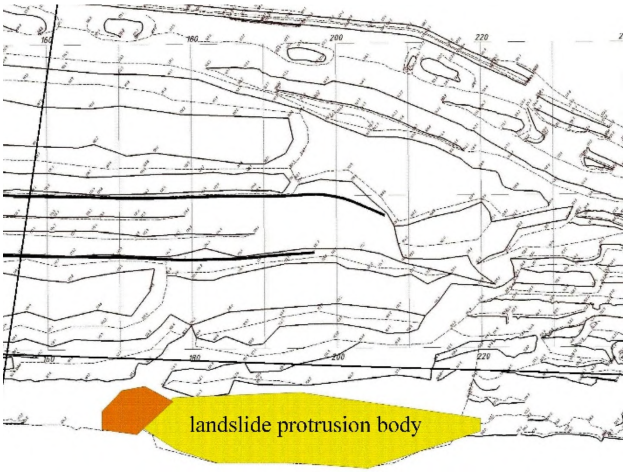

Fig. 1. Schemes of the formed landslide and placement of boreholes.

Deformations in the form of landslide with the following parameters appeared on the section of the south-western side of the dump No 2: the length of the landslide manifestation was 410 m; the depth on average was 7 m; the volume was 850 thousand m^3; landslide area is 85 thousand m^2. It should be noted that previously no deformations were observed in this part of the dump. In the area of the dump formation there is a complex relief with a hollow. The negative aspects include the very low strength of rocks placed into the dump (mainly clays, loams), which have a high plasticity at a natural humidity of 21 - 25%, the sole of which also contains different by their physical and mechanical properties loams.

Therefore, the following **tasks** need to be solved: using geophysical methods to determine the presence of aquifers and their impact on the dump, to consider possible options for the development of works on the dump taking into account the formed deformations, to determine the stability of slopes according to the proposed models of development, to choose the best technical and economic indicators.

4 Purpose

To solve the tasks it is necessary to determine the most economically feasible option for the development of works on the dump where the processes of landslide deformation and protrusion in its sole outside the land allotment of the enterprise.

5 Methodology

To solve the tasks set force in this work, the following research methods were used: geophysical method of the Earth's natural pulsed electromagnetic field (NIEMEF) - for the forecast estimation of the risk of formation of new centers of geodynamic phenomena and development of the measures to prevent them; the method of algebraic addition of forces - to establish changes in the stress-strain state of the rock array; computer modeling to substantiate technological solutions by options; graphical and analytical method - to calculate the stability of slopes by various options of the development of mining operations on a dump; economic comparison of accepted technological decisions - to define a rational variant of formation of the final dump contours.

6 Selection of initial data

The boundary of the dump No 2 is within the hollow and the dump occupies its entire area (see Fig. 1). The body of the protrusion in the plan is a complex isometric figure, the length of which is 490.6 m, and the maximal width from the outer boundary (on the arable field) to the boundary of the joint behind the sole of the protrusion with the ledge of the dump 111.9 m. The protrusion surface is presented by the complicated relief with atypical height differences complicated by violations (cracks). The body of the protrusion has: 46 thousand m^2 - the area of the base of the body of the three-dimensional model of the protrusion; 700 thousand m^3 is the volume of protrusion. In addition, there is a scree formed to the west of the protrusion due to a violation of the density of the ledge when moving rocks during the protrusion. It has the form of a dump ledge with an average height of 25 m and a length of 82.6 m, and a width of 78.5 m. The area of the scree base made 6.5 thousand m^2. The total volume (talus and protrusion) amounted to 850 thousand m^3.

Geo-mechanical studies of changes of the stress-strain state in the studied area were conducted in order to forecast the risk of formation of new centers of geodynamic phenomena and develop measures to prevent them. The geophysical method of the natural pulsed electromagnetic field of the Earth (NPEMEF), which was applied, is used in engineering and geological research to clarify the localization of processes and phenomena occurring [22]. An example of interpretation of measurement results is shown in the Fig. 2.

The rocks that form the basis of the dump: the modern division (q_{iv}) is represented by a soil-vegetation layer with a thickness of 0.1 - 0.5 m, upper quaternary sediments q_i are represented by two varieties: pale loams, pale yellow loess and brownish-yellow with the thickness of up to 4-4.5 m; middle quaternary sediments q_i are represented by two types of brown-pale and yellow-brown loams with a thickness of 0 to 8 m; brown and red-brown clays, which belong to the undismembered neogene-quaternary sediments lie in the form of lenses with a thickness of 1.6 to 13 m; below there are the primary kaolins with a thickness of 2.8 to 20 m.

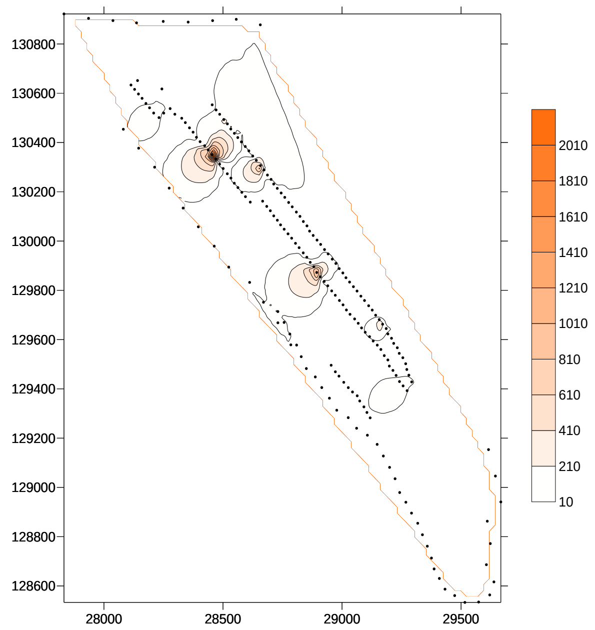

Fig. 2. Example of site interpretation of the study results using the NPEMEF method for creep zone (sliding rocks) at the dump No 2 in the Z plane (Color scale in mV)

7 Organization of calculations

As a result of geophysical studies of the dump No 2 of the Petrovsky open mine of the PJSC “COMPE” by the method of NPEMEF the following was established: the north-eastern side of the dump is currently stable, so the following description applies to the south-western side; cracking in the rock mass of the dump at the time of the study mainly occurs in the northern part; areas of rock landslides at the time of research are established in the northern part and in the area of deformation; the stress-strain state of the rock mass of the dump №2 is registered in the south-western section and at the workplaces of the equipment in the middle part of the dump; water migration is superficial; the groundwater mirror in some areas is in the range from 1.5 to 10 m; deep accumulation of moisture is not observed, as the modern and ancient relief promote drainage, and inflows of surface waters should be regulated by means of the water drainage channel.

The direction of groundwater migration along the axis of the hollow from the north to the south. It should be noted the possible presence of lenticular accumulations of water in the northern and middle part of the dump. The accumulation of groundwater in such lenses can lead to landslides in these areas.

To determine the stability of the dump the method is used proposed by the institute “VIOGEM”. From the upper edge of the slope shown in the Figure 3 in one of the scales adopted for surveying documentation, the value of the width of the slide prism *a* and the vertical value of H_{90} are set.

Studies have shown that the sliding surface of the slide prism for these conditions is smooth curvilinear, the form of which is close to round-cylindrical. The location of the most stressed surface in the rock mass adjacent to the slope coincides with the location of the calculated surface with a minimum safety factor. This surface is defined by stability calculations. Taking into account the obtained physical and mechanical properties of rocks, as well as when testing wells, it became clear that the rocks are not flooded. Therefore, the calculation is carried out under condition of limit equilibrium of forces.

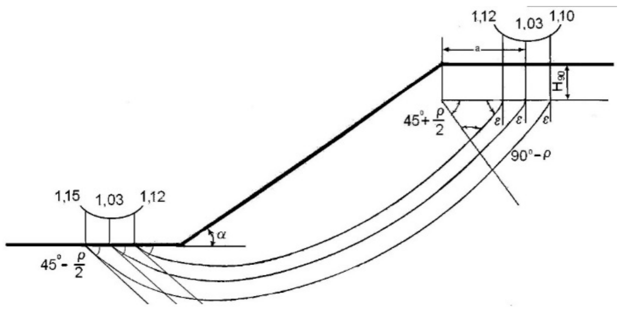

Fig. 3. The position of the calculated surfaces on the slope of weak rocks (ρ<13°, α<ε)

The condition of limit equilibrium in the algebraic addition of forces on the most stressed surface is written as follows:

$$\frac{\sum_{i=1}^{n} P_i cos\varphi_i \cdot tg\rho_n + \sum_{i=1}^{n} k_n l_n}{\sum_{i=1}^{n} P_i sin\varphi_i} = \frac{tg\rho_n \sum_{i=1}^{n} N_i + k_n L}{\sum_{i=1}^{n} T_i} \quad (1)$$

where P_i – the weight of the elementary blocks into which the prism is divided in the array, adjacent to the slope, limited by the most stressed surface, t;
l_i – square of the base of elementary blocks, m^2;
φ_i – incline angle of the base of elementary blocks, degrees;
ρ_n, k_n – features of resistance of sliding rocks, decreased by *n* times.

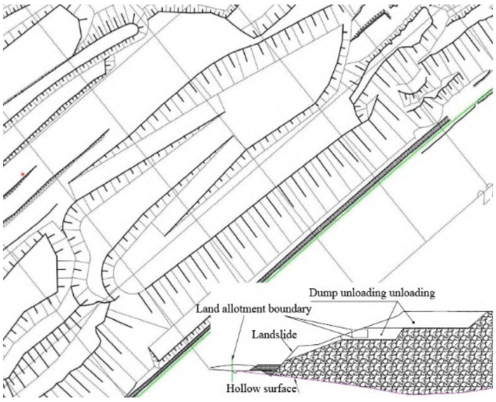
7.1 Options of the dump forming schemes

During the work performance it is offered to consider 3 variants of the decision of unscheduled works on the landslide liquidation (fig. 4).

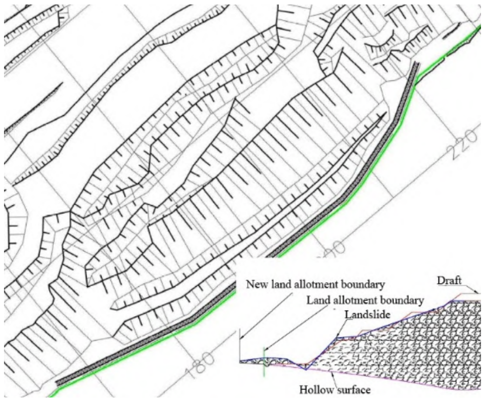
Option 1. Removing the landslide to the boundaries of the land allotment without allocating of additional land and determining the possibility of further storage the overburden rocks in this area (Fig. 4).

Option 2. To carry out land allotment on the slide section from slide action and to define possibilities of the further of overburden rocks in conditions of the formed landslide on the dump (Fig. 4).

Option 3. To carry out land allotment on a slide section in conditions of the formed landslide on the dump, to form a support prism from slide action and to define possibilities of the further storage of the overburden rocks (Fig. 4).



Option 1



Option 2

Option 3

Fig. 4. Technological schemes of the options for solving the problem of landslide.

Taking into account the determination of the residual capacity of the dump No 2, calendar plans for storage of the overburden rocks have been developed according to the options (Fig. 5), in thousand m^3.

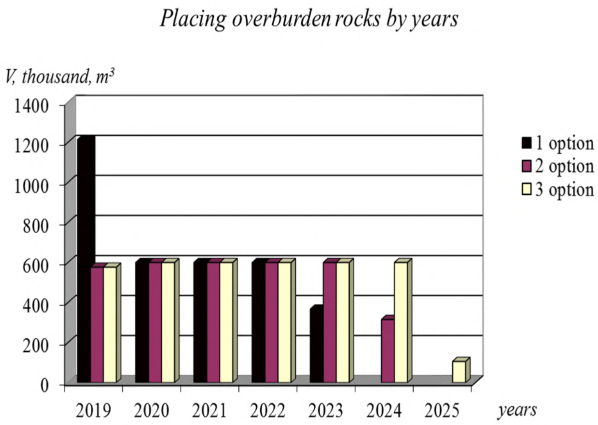


Fig. 5. Placing overburden rocks by years at the dump according to the work development options

7.2 Calculation of stability parameters

For different variants, taking into account the obtained sections, the safety factors were set. The calculation scheme for the option 3 is shown in the Fig. 6. Calculations were reduced to the search for sliding forces and restraint forces.

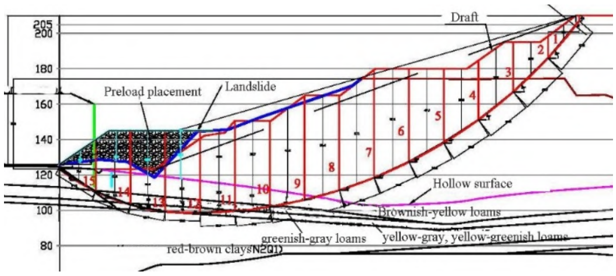

Fig. 6. Graphic part of the calculation of stability in the section surveying axis (s.a.) 180 (with loading)

At the initial stage, the following data on the safety factor were obtained (table 1) around the perimeter of the whole dump.

Table 1. Summarized table of the safety factors

	Current position	After slide removal	Draft state	Draft state with the loading by rock	Draft state with loading
Open mine 180(well PO-2, slide)	1.1	1.01	1.0	1.3	1.26
Open mine 180(well PO-7)	0.71	–	0.99	–	1.18
Open mine210(well PO-3, slide)	1.24	1.06	Almost current state	1.49	1.42
Open mine 210 (well PO-6)	–	–	1.24	–	–

Option 1 provides the removal of the landslide to the boundary of the land allotment. It is not possible to remve only landslide due to the reduction of the safety factor. To reduce the load on the dump, the option of removing a part of the rocks on the upper horizons between the marks +175 to +160 m is considered. According to the calculation data the safety factor at the survey open mine 210 s.a. for the dump after removal of the rocks with the formation of the resulting slope 15º makes 1.43 (Table 2). This figure is sufficient for a stable position.

When calculating the safety factor in the area between the marks +160.0 and +124.0 m, it was determined that this area is not stable (Ky = 0.87, Table 2). That is, significant volumes of landsliding are possible in this area.

Table 2. Summarized table of the safety factors

Open mine s.a.	**The total stability of the dump** after removal of the upper tier of the dump (+174.0 and + 160.0m) and bringing its slope to 15º	Stability of the **lower** tiers after removal of the upper tier	The stability of the lower tiers **after removal of the second tier** (+160.0 and +150.0 m) between s.a. 180 and s.a. 190	Stability of the lower tiers **after removal of the second tier** of the dump (+160.0 and +150.0 m) and **backfill of the support prism** between s.a. 180 and s.a. 190
s.a. 210	1.43	1.34	–	–
s.a. 180	1.62	***0.87***	***0.94***	**1.11/*1.24**

* – stability factor after laying a steep slope with the help of the excavator ESh-10/70 (between marks +150.0 m + 123.0 m)

The area that is prone to slide in the open mine s.a. 180 (Fig. 4, option 1) is marked with cells. To reduce the pressure of the upper rocks in the area of 160 m, it is necessary to remove a part of the rock mass on another horizon with marks from +160, 0 to +150.0 m. However, the stability in the area increases only to a factor of 0.94. Thus, this measure is also not enough. It is proposed to carry out backfilling with a prism at the base of this section after unloading the dump from the rocks of the upper horizons in the area between the surveying sections s.a. 180 and s.a. 190.

That is, according to the option 1, it is proposed to carry out a set of measures for removing the dump and return it in the boundaries of the land allotment in the area between the sections of the s.a. 180 and s.a. 190. Namely, the excavation of a part of the dump rocks in tiers with the marks of the first excavation tier +174.0 and +160.0 m and the second tier in the area between the sections s.a.180 s.a. 190 with marks +160.0 and +150.0 m. To increase the safety factor, it is proposed to move the slide rocks to the base of the dump and form a support prism with an upper mark of +129 m. The height of the support prism is 9.0 m. Landslide rocks are removed by excavator, are moved by auto dump trucks to the bottom of the dump and the supporting prism is formed by a bulldozer. The width of the top part of the prism is 20 m. The safety factor in the area of the dump between the marks + 1K50.0 and +129 m will be 1.11.

After removal of the part of the dump on the upper tiers where there was a landslide and the creation of a loading prism to the mark of +129.0 m to ensure the normative stability of the dump is proposed to laying down on the section with a steep slope using an excavator EK-10/70. 2. The summarized table on the safety factors with the removal of the dump landslide and the return of the dump in the boundaries of the land allotment is given below.

7.3 Recommendations for the obtained data on the stability of the dump slopes

According to the performed mining and geological studies, the rocks at the base of the dump do not have groundwater.

The calculated values of the open mines (see Table 1) indicate that it is possible to remove the landslide, but this will reduce the stability of the dump. Thus, the safety factor in the open mine s.a.180 under the current position is 1.1 and after removal works, it will be 1.01, which corresponds to the limit stability state. Thus, at some point the dump will be in a relatively stable state, but in the event of external factors, changes in the properties of the clays' rheologies at the base of the dump and in the dump, getting water and others, it will be prone to repeated landslides.

For open mine 180 in the area of drilling PO-7 will the stability adverse conditions will also appear. Measures to increase the stability is the reduction of the resulting slope inclination angle of the dump or the formation of the loading embankment at the base of the dump.

The data of the safety factor in the open mine 210 (Table 1) indicate that the current position in the sliding area of the dump is in a stable state (the safety factor is - 1.24), after removal works this figure will decrease to 1.06, i.e. the dump will be in a state of the limit equilibrium. At the moment of the slide removal at an unfavorable background (moisture, dynamic loadings, static loadings, change of clays' properties) repeated slide signs can appear. To increase the stability of the dump as well as when considering options for the open mine s.a. 180 it is proposed to load the dump in bulk at the base. The rocks removed from the open mine and stacked on the dump were taken into the calculations as the loading material.

Conclusions on the possibility of the option 1 (Table 2): It is proposed for removal the dump and returning it in the boundaries of the land allotment in the area between the sections of s.a. 180 s.a. 210 to implement a set of measures. To carry out excavation of waste rocks in tiers with the marks of the first excavation tier +174.0 and +160.0 m and the second tier in the area between the sections of s.a. 180 s.a. 190 marked +160.0 and +150.0 m. To increase the safety factor, it is proposed to move the slide rocks to the base of the dump and form a supporting prism with an upper mark of +129 m between the sections of s.a. 180 and s.a. 190, i.e. not along the entire length of the landslide, but only in the section with a length of approximately 160 m. The safety factor in the area of the dump between the marks +150.0 and +129 m according to the calculations will be 1.11. To increase the dump slope safety factor in the section, it is proposed to lay down the slope with an excavator EK-10/70. The EC excavator moves the rocks to the dump site with the mark +160.0 m, from where it is loaded into dump trucks with the help of an excavator and moved to the dump.

Option 1. Removal of the landslide, as well as the extraction of waste rock on the upper tiers is carried out by a hydraulic inverted shovel type excavator, and the laying down of the slope with EK excavator. Removal of the rock mass is carried out by the dump trucks to the dump where they are unloaded and placed by means of the bulldozer [23-25]. To remove the landslide, it is necessary to form a road, to lay down the power line and drive the EK excavator to the place of the landslide to the upper tiers. Landslide rocks are partially used to form the loading prism for this purpose a bulldozer must be used. When the landslide removal is finished with the help of an excavator, a trench of the water drainage ditch is formed and strengthening works are done with the placement of concrete slabs inside the ditch.

Option 2. The formed landslide remains within the existing limits. The works on construction a bypass ditch (see option 1) along the landslide with reinforcement works and the placement of concrete slabs are performed. Legislation regulates the issue of land allotment for the dump.

Option 3. The same works are performed as in the second option, but the road from the dump to the landslide is being reconstructed. A reloading point is organized at the dump. At the reloading point, the rock is shipped into dump trucks by an excavator and delivered to the landslide place. A pioneer embankment on the horizon of +145 m is formed in the area of the landslide site. The formation of pioneer and loading embankments is done by a bulldozer. The rock mass delivered by dump trucks is unloaded on the loading embankment and formed by a bulldozer.

From the point of view of technological decisions the third option is most effective, which allows to place in addition volumes of overburden rocks both in a loading embankment (385.14 thousand m^3), and to form a dump with a height within design contours providing the stability of the dump. Also, the technological solution is the formation of the dump with the landslide removal (option 1), for which it is first necessary to perform works to reduce the resulting slope angle by removing a part of the tiers of the dump and forming a loading prism at the base of the landslide.

Decisions on the effectiveness of options were made taking into account economic indicators.

To determine the economic indicators of options for the development of works on the dump the indicator *PVI* (Present Value of Investment) was used [26], which is calculated to obtain an idea of the current value of the total investment costs of the enterprise over the years. The decrease in this indicator against the background of an increase in discounted incomes from investments indicates an increase in their efficiency. The analytical expression of this indicator is as follows:

$$PVI = \sum_{j=1}^{m} \frac{I_j}{(1+i)^j} \quad (2)$$

where I_j – annual investments during *m* years.

To determine the amount of PVI per 1 m^3 of the rock mass, the costs were reduced to the initial moment of time, taking into account the discount rate of 15%. The reduced costs under the option 1 make only 68555.2 thousand UAH.

PVI per 1 m^3 of the rock mass will be:

68555.2 / 3381.675 = 20.27 UAH/ m^3

Thus, the net present investment costs under the first option will make 20.27 UAH per 1 m^3 of works related to the formation and reclamation of the dump.

Similar technical and economic indicators are determined under the 3 option. The net present costs under the option 3 make only 60081.03 thousand UAH. Thus, the net present investment costs under the option 3 will make 16.31 UAH per 1 m^3 of works related to the formation and reclamation of the dump.

60081.02 / 3682.985 = 16.31 UAH / m^3

Given that the target criterion for the effectiveness of the investment options is to minimize the cost of dump formation, it is the option 3 should be considered as one that provides a more rational use of investment resources.

According to the results of calculations in the table 3 the technical and economic indicators for the formation of the final contour of the dump No 2 on the CO MPE are shown.

The main operating costs for the formation of the dump over the years are shown in the Fig. 7.

Table 3. Technical and economic indicators

Name of indicators	Unit	Value for development	
		Option 1	**Option 3**
1. Dumping time	years	5	7
2. Total volume of overburden rocks stored	Thousand m^3	3381.675	3682.985
3. Mining and technical reclamation: -volume of cover soil	Thousand m^3	162.216	163.108
4. Biological reclamation: - Furrowing; Number of seedlings - trees - bushes	s.a., units	185248.0 63577 15578	195232.0 67005 16418
5. Mineral fertilizers	kg	6883	7260
6. Irrigation water during planting	m^3	1030	1086
7. Water for vegetative irrigation	m^3	4122	4344
8. Capital investments for the dump formation:	Thousand UAH	22792.752	15696.563
9. Operational costs - for mining and technical reclamation; - for biological.	Thousand UAH	15152.125 11505.066	15763.871 12150.998
10. Agricultural production costs	Thousand UAH	150.480	150.480
11. Net present total operating costs	Thousand UAH	68555.2	60081.02731
12. Total net present investments per 1 m^3 for forming and reclamation of the dump	UAH	20.27	16.31

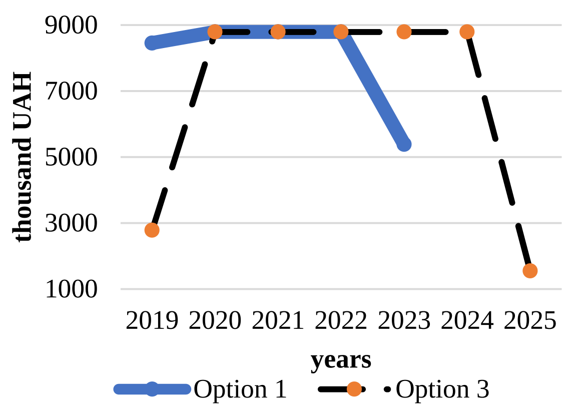

Fig. 7. Costs under the chosen options of the rock storage on the dump

8 Conclusions

1. As a result of the research of the dump No 2 of the Petrovsky open mine of the PJSC "COMPE" the following was established: the north-eastern side of the dump is currently stable, so the further description applies to the south-western side; cracking in the rock mass of the dump at the time of the study mainly occurs in the northern part; water migration is superficial.

2. During the operation of water-bearing communications (gutters) and the lack of the proper surface drainage, it is possible to soak the loess loams, which will reduce the deformation, strength characteristics and subsidence of the base soils, and as a consequence, negative processes of the rock mass extrusion [27-30].

3. Removal of the dump landslide to the boundaries of the land allotment can lead to repeated manifestations of rock slide. The dump will be in limit equilibrium, which is dangerous for machinery and people working at the bottom of the dump [31-34].

4. When forming the dump taking into account the formed landslide, there are two solutions for the further construction: the first one is the reduction of the dump height with observance of the angle of the resulting slope within 16 degrees and the second - construction of loading embankments in the formed landslide area. Loading embankments reduce the resulting angle and create additional load for the retaining forces.

5The calculation of costs for the formation of the final contours of the dump No 2: calculated costs for the creation of a drainage ditch, the land allocation costs, as well as operating costs for the formation of the main dump and its reclamation. It can be seen from the above calculations that the capital costs under the option 1 exceed the capital costs under the option 3 by 6918.549 thousand UAH. However, operating costs for the formation of the dump and the cost of reclamation are lower by 4434.19 thousand UAH and 1257,678 thousand UAH respectively. In order to be able to compare the costs of the projects, the net present investment costs for each of them are related to the formation and reclamation of the dump. Calculations have shown that the unit costs under the option 3 are UAH 3.96 less than the same indicator under the option 1. Thus, according to the criterion of minimizing the unit costs for the formation and reclamation of the dump No 2, the option 3 is more appropriate for implementation.

Abstract. At mining and processing complexes, many parameters today are evaluated from the point of view of the total process from geology to the final product. Changes in certain mining parameters inevitable lead to the changes in the following downstream processes. In this article, the focus is on the ore fragmentation, which is one of the most important parameters in many mines as it affects the downstream ore preparation and processing efficiencies, productivities and costs. In most of the cases, the cheapest way to improve the fragmentation of the ore is by changing the drilling-and-blasting design parameters. It of course increases the mining costs, but at the same time decreases the costs of the following processes, which are normally significantly higher. Therefore, authors of this article propose a new way of optimization of the drilling-and-blasting process by introducing new blast design modifications. Based on the analysis, research of the scientific information and the mining practise, the authors discuss the way of creation of the preliminary stress in the block of the open pit and hence improving fragmentation. Physical experimental blasts in "Belaya Gorka" open pit were performed and shown positive results reflecting a potential for continuation of the research in this direction in the future.

1 Introduction

Mining industry is very competitive and requires mining companies to constantly improve their processes, costs and safety. From the sustainability point of view, there other environmental and safety issues at the existing mines and potential mining projects as well [1, 2]. From the technical point of view, many mines have problems with the decreasing grades of the components in their ores, increasing depths, more complex hydrogeological and geotechnical conditions and hence need new approaches to the processes of mining and processing, which today are not considered separately anymore as it was just one or two decades ago. One process affects the other due to their sequential link between each other and of course any implementation should be evaluated taking into account its complex effect on the company as a whole.

Today, the process of intensification of processing (including heap leaching) is done by applying various effects to the ore (physical, mechanical, chemical, biological), most of which are aimed at improving efficiency and reducing the cost of extraction of valuable components. Very often, ore fragmentation becomes one of the most important characteristics [3]. Therefore, for example, to obtain the required particle size distribution for heap leaching, ore coming from the open pit goes through several crushing stages. Of course, such mechanical crushing is expensive and sometimes makes from 8 to 18% of the total operating costs.

At the same time, the operating cost of the open pit mining is often several times lower than the cost of processing [4, 5], respectively, the cost of ore preparation during drilling and blasting operations is cheaper than mechanical preparation [6].

Therefore, it is obvious that the ore fragmentation during the drilling-and-blasting operations at the mining stage affects the following operations at the stage of processing and could give a positive economic effect to the company as whole.

Many technologies are used in the world today to improve the efficiency of blasting. For example, in works [7, 8], the authors describe the effect of empty blast holes on the nearest charged blast holes. In both cases, process modeling was performed to understand and describe the stress distribution in the mining block. Also, the authors of [6] do a calculation, where they show that more work done during the drilling and blasting process to improve fragmentation, save energy and work on the downstream processes, which further shows how the increase in the drilling and blasting cost leads to the decrease in the cost of the following crushing and grinding.

Considering that there are several ways to perform research on the new technologies, such as simulations [9], digital twins [10] or actual physical tests at the mines sites, where possible, authors of the work have performed physical blasting experiment at one of the

* Corresponding author: abencl@mail.ru

open-pit mines. Of course, at the beginning, all the conditions and actual information on the performance of the mine were gathered for the future comparison with the research work's results.

2 Research

Blasting is a complex process, which is still not fully understood, even though a lot of research work is conducted to improve it. Many works are performed at certain conditions, which are hard to be replicated in the mining site, because every blasting block is different and it is impossible to consider the main parameters so that can be utilized as general ones. Knowing that the blasting process has many important characteristics affecting its efficiency, the research work has focused on one of the main ones, which is the stress wave that plays the main role in the mechanism of fragmentation of rocks by blasting.

2.1 Calculation methods

The method for calculating the parameters of stress waves was developed by the authors of [11, 12]. This technique was improved in works [13, 14, 15], while the author of work [13] tried to take into account the detonation velocity and the actual length of the charge. The considered algorithms and programs were strongly focused on the types of computer technology of that time and were not very suitable for carrying out a large amount of calculations.

He calculated the geometric parameters of the wave front arising around a charge of cylindrical symmetry, introduced and experimentally determined the rate of decrease in the conical section of the wave front. However, at the stage of determining the influence of the design parameters of a charge of cylindrical symmetry on the formation of a stress field in an unlimited medium, he did not take into account such an important parameter as the diameter of the charge. As a result, the calculation he proposed makes it possible to only qualitatively estimate the shape of the wave front, depending on the length of the charge and the detonation velocity.

The author of [14] eliminated these shortcomings, but considered the process of formation of a stress field from an elongated charge, which does not fully describe the real picture of the effect of stresses on the fracturing of a rock mass, since in practice, the blast holes are not blasted separately, but rather as a whole block of the blast holes.

In [15], a method for the numerical calculation of the parameters of the wave field of stresses from four blast hole charges is proposed. However, this technique did not take into account such important parameters of the blast-holes as the direction of initiation, the number of points of initiation. In addition, only radial stresses or stress wave components along the coordinate axes were calculated, which made it difficult to analyze over the entire calculated field.

To improve the quality of the ore to be broken and to reduce the cost of crushing it before leaching, a technology of crushing has been developed using the preliminarily created stressed state of the massif.

In our case, to study the influence of the preliminary stressed state of the massif on the quality of ore breaking, experimental blasts were carried out in the open pit, which has drilling-and-blasting process for the initial ore crushing.

2.2 Research site

The object of the study is the section of "Belaya Gorka" site, which is a part of the Rodnikovoye deposit, administratively located in the northern part of the territory of the Kokpektinsky district (on the border with the Zharma district) of the Eastern Kazakhstan region of the Republic of Kazakhstan.

Overall, the technological process at the site is fairly standard for the mining complexes. Mining and processing are performed with a cycle consisting of:

- drilling and blasting with the use SBU-100GA-50 drills;
- loading using backhoe excavators with the 2.2 m^3 bucket for waste and 1 m^3 bucket for ore;
- transportation of the mined ore to the ore stockpiles and waste to the waste dumps using 40 tonnes payload Belaz trucks;
- from the stockpiles the ore is sent to the crusher for preparation;
- prepared ore is sent to the heap leach pad for extraction of gold.

The mine has average grades of approximately 1.44 g/t. At the same time, because heap leaching is utilized the cost of processing is low, but the recovery is low as well (around 62%). Other geological and technical conditions of the mine are:

- Average uniaxial compression strengths of the rocks 78.2 MPa (46-111 MPa range) in the dry state and 55.6 MPa (5-97 MPa range) in the wet state respectively;
- Oxide and sulphide materials are present at the mine;
- Rocks are fractured, but pit walls are stable with some local failures;
- Batter face angles in the pit are 45-60º, with steeper parameters in the eastern (50-55º) and western walls (55-60º);
- Swell factors variate depending on the rock types from 1.27 to 1.75 (1.6 in average);
- Specific gravity also varies from 2.14 t/m^3 for the soft weathered material, 2.58 t/m^3 for the hard oxidized material and 2.72 t/m^3 for the primary hard rocks.

Based on the mining technical conditions of mine, the method of vertical blast hole charges with a short-delayed blasting was adopted. The blasting block that was chosen for the experimental blasts consisted mainly of sandstones and siltstones.

Drilling and blasting parameters were settled at the mine in the previous years of operation. However, some them, like burden, stemming and charge height are variable due to the presence of many different rock types.

 https://doi.org/10.1051/e3sconf/202128008015

The list of the main blast design parameters are reflected in the table 1.

Table 1. Drilling and blasting design parameters.

Name	Unit	Parameter	
		ore	**waste**
Sub-bench or bench height	m	5	10
Blast hole diameter	m	0.11	0.11
Explosive density (grammonite used for the experimental blasts in the pit)	t/m^3	0.9	0.9
Specific gravity of the rocks	t/m^3	2.41	2.72
Burden of the first row of the blast holes along the bottom of the bench	m	4.8	6.6
Subdrilling	m	1.0	2.0
Blast hole depth (drilling depth)	m	6.0	12.0
Stemming	m	3.1-3.4	4.3-4.6
Charge height in the hole	m	2.9-2.6	7.7-7.4
Explosive specific consumption per volume of rock	kg/m^3	0.6	0.6
Burden	m	3.5-7.0	4.6-8.0
Spacing	m	3.2	4.1

The main explosives, which are used at the mine are:

– ANFO for the soft dry areas (mainly overburden and oxide ore);

– FortisExtra 70 for all the other ore and rock types;

– Grammonite is sometimes used as a replacement for the above-mentioned explosives.

SenatelMagnum with the cartridge diameter of 34 or 90 mm is normally used as a primer. However, in some cases, ammonite with the cartridge diameter of 34 or 90 mm and trinitrotoluene blocks (T-400) are used as well as a replacement to the SenatelMagnum.

For the conditions of this deposit, the blast holes in the ore blocks is drilled to the depth of 6 meters, so that the amount of explosive per 1m of the blast hole is P = 9.5 kg, the weight of the charge in the blast hole, taking into account stemming height of 3.1 m is Q_{bh} = 27.6 kg.

3 Discussion

It is known that the process of fragmentation of rocks by blasting occurs in very quickly and depends on many factors, which are not easy understand and research. There is still no internationally accepted exhaustive theory of the mechanism of fragmentation of rocks by blasting.

Assuming that during the process of blasting, the fragmentation of rocks is mainly determined by the energy of stress waves, the effect of blasting of a single concentrated charge in an unlimited homogeneous medium can be represented in the following form:

– During the blast, the walls of the charging block are instantly affected by the enormous pressure of the blasting products and a shock wave is generated;

– The compression stress at the shock front increases abruptly, the velocity of its propagation exceeds the speed of sound in the rock;

– The crushing resistance of even the toughest rocks is several times lower than the magnitude of the stresses arising at the wave front at the walls of the charged block;

– Particles of the rock receive radial movements and are displaced after the front of the shock wave;

– After the shock wave has passed, the pressure in the charged block drops, and the rock near the charge begins to expand towards the center of the charge and unload;

– As a result, a zone of highly deformed rock is formed;

– As you move away from the charge, the blasting energy is transferred to the ever-increasing mass of the medium, due to which the specific energy (J per 1 cm^3 of the block) decreases significantly. Compressive stresses drop rapidly with distance.

3.1 Rock crushing zones understanding

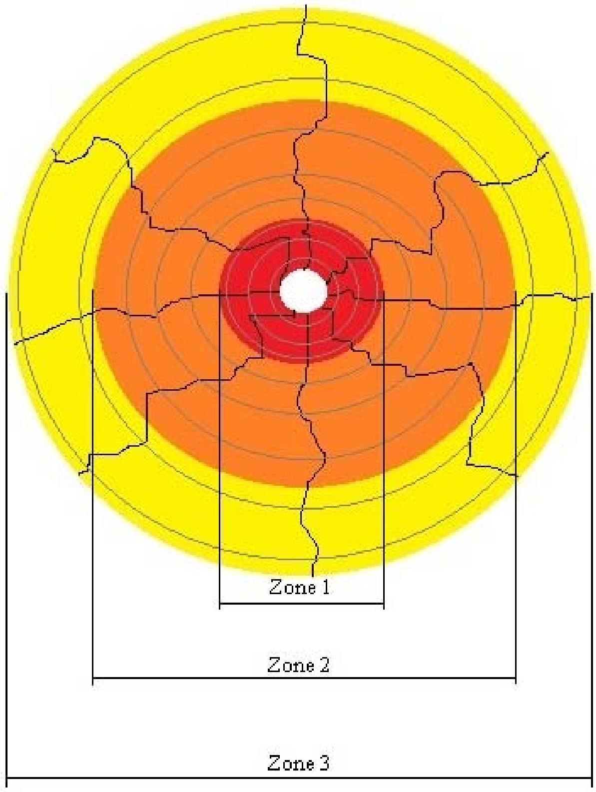

Fig. 1. Various zones arising from hole blasting (red – zone 1, orange – zone 2, yellow – zone 3.

Thus, when blasting holes in a quarry or pit where hard rocks are mined, several zones are distinguished [16]:

– the first zone is compression and plastic deformation, which, depending on various factors, is usually within 3-7 radiuses of the charge from the blast hole;

– the second zone - elastoplastic deformations and primary fracturing, in which rocks are crushed when subjected to tangential stresses creating tension. It is usually within 120-150 charge radiuses;
– the third zone is elastic deformation and fracturing, which, respectively, is outside the 150 radiuses of the charge.

All the above-mentioned zones are schematically reflected on the figure 1.

3.2 Blasting in a block

Thus, if we consider a theoretical block consisting of four blast holes located in a row, it can be understood that the least affected area is usually located in the center, at an equal distance from all holes, as shown in Figure 2.

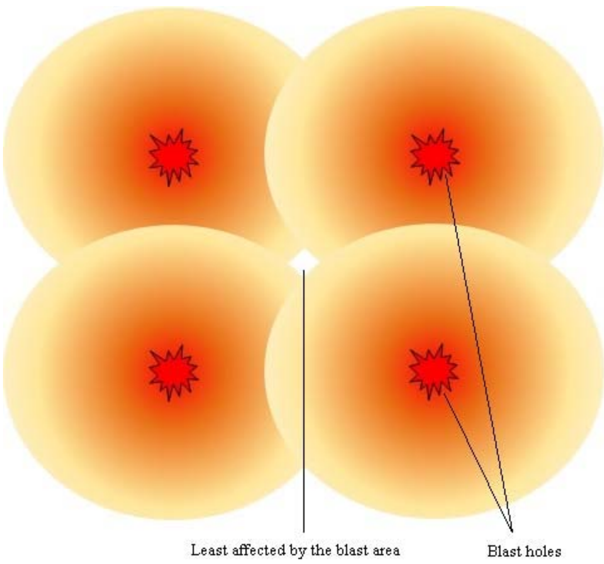

Fig. 2. Theoretical block, showing effect of the blast at the distance from the four holes, where color from red to white shows the intensity of fragmentation (white area in the center is the least affected by the blast)

Considering that, one of the major challenges in the production blasting is to have a rock mass with specific particle size distribution. The solution to this problem is possible by studying the above data, as hole as on the basis of a full research of the mechanisms of fragmentation of the rock, when impulsive loads are applied, which allows us to determine the optimal parameters of the pulse in specific mining conditions.

In our case, two or three rows of blast holes are used in the pit to fragment rocks. According to calculations, knowing the amount of the energy released by 1 kg of the explosive, and having the such parameters as the weight of explosive in one blast hole from the Table 1, the total potential energy of one hole is equal to:

$$E_p = E_e\, m_h\, 4.1868 \qquad (1)$$

where E_p – potential energy of the blast per one blast hole;
E_e = 1025 kcal/kg - energy released by 1 kg of the explosive;
m_h – mass of the explosive in one blast hole.

So, the total potential energy of the blast per blast hole equals to 118 444.57 kJ/kg, with a detonation speed of 3500 m/s, which is the rate of increase of the initial load on the hole walls.

On one side of the hole, this load is applied to the volume of the rock mass, one side of which is the bench face, i.e. free face, which is not loaded. On the opposite side, the blast shock wave coming from the blasting sets the momentum for the particles of rock. First, the particle velocity is calculated using the formula below:

$$\vartheta = \sqrt{\frac{2\eta q Q}{p}} \qquad (2)$$

where η = 0,05 – blast efficiency coefficient;
q = 0,6 – explosive specific consumption from the Table 1, kg/m^3;
Q = 4291 – specific heat of the blast of the specific explosive, kJ/kg;
ρ = 2410 – specific gravity of the rock, kg/m^3.

So, the particles velocity for our specific scenario is approximately 0.33 m/s.

Further, having calculated the velocity of the rock particles during the blast, it is possible to calculate the kinetic energy of the blast, required to throw away the first layer of rock with a volume of V = 227 m^3 using the following formula:

$$E_k = \frac{m\vartheta^2}{2} \qquad (3)$$

where m = 547 t – mass of the 227 m^3 of rock of the first row;
ϑ = 0.33 m/s – velocity of the particles of the rock during the blast.

The kinetic energy required to throw away the first layer of rock would be equal to E_k = 29.8 kJ. The amount of energy released from the blast hole charge is E_{bh} = 118 444.57 kJ, which means that a little energy is used for blasting of the first row and the rest of it is dissipated in the other blasting zones, used for the heat generation and etc.

Knowing this, blasting zones can be calculated using the known radius of the charge (55 mm as the hole diameter is 110 mm) for the specific conditions of the mine:
– Zone 1 is assumed to be 7 charge radiuses and equal to 0.385 m;
– Zone 2 is assumed to be 120 charge radiuses and equal to 6.6 m;
– Zone 3 is assumed to be 150 charge radiuses and more, and equal to 8.25 m.

Having studied in more details the technology of fragmentation of rocks in the open pit, we made a proposal for the classical technology of accounting for the initial stresses obtained from the blasting of the first row of holes, which made it possible for us to clarify the delay time of the second row of blast holes.

Further research of the process of fragmentation of rocks has shown that when the blasting of the second row with a delay, the initial stress is used, only in the section between the first and second rows of blast holes, and most of the area is fragmented by crushing the rock using the power of the blast wave, which several times exceeds the ultimate strength of the rock mass. The remaining part has mainly closed cracks, which, when blasting the next row of holes, do not contribute much to crushing. In the interval between the side of the open pit and the first row of blast holes, the rock is crushed by the tension wave, which occurs when the blast wave is reflected from the free surface of the pit wall.

4 Proposed technology

To use the initial stress for the purpose of crushing the rock during the blasting of holes in a block, an updated blast design layout of the holes shown in Figure 3 was proposed.

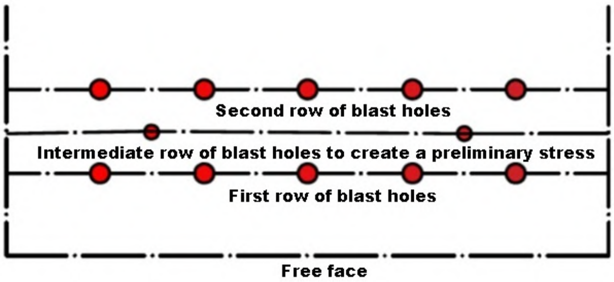

Fig. 3. Proposed holes layout (two standard rows of the blast holes and one intermediate).

In order to create an initial stress in the entire area of the breakage intended for fragmentation, an additional row of charging holes is created, and the blasting power of additional holes should not exceed the ultimate strength of the rocks being crushed. The burden is determined for each case separately, taking into account the mining and geological conditions of the field and the radiuses of the blasting zones. The distance to the additional row of holes and the distance between the holes are selected taking into account the burden of the first row of holes, and all holes along the surface must be at an equal distance from these holes. Thus, an elastic stress wave can be created, which will not fragment the rock, but rather create the initial stresses for the further more homogeneous fragmentation of rock by the main blast. Overall, the assumption is that the best place for the intermediate holes is at the border of the second and the third blasting zones.

The blasting of the first row of blast holes must be made at the moment, when the wave of the firstly blasted row of intermediate holes passes the first row of blast holes and creates an initial preliminary stress. In order to match the timing, the delay time between the intermediate row and the first row of the blast holes should be calculated. The effect obtained with such blast delay will provide interference of stress waves, which will facilitate their action and increase the effect of fragmentation produced in the block.

The delay time (interval) between the initiation of the intermediate and the first row of the blast holes is determined using the following formula: [17, 18]

$$t = \frac{\sqrt[2]{a^2 4\, W^2}}{\vartheta_s} \qquad (4)$$

where a – is the distance between charges, m;

W – burden of the blast holes along the bottom of the bench, m;

ϑ_s - velocity of shock wave propagation in the rock mass, m/s.

When using the proposed formula above, the average delay should be equal to 32 ms.

5 Results

To establish the influence of the initial or preliminary stress on the quality of ore crushing, a new blast design was proposed. The existing blast design of the “Belaya Gorka” site was adjusted with an addition of an intermediate row of blast holes, which were placed at the border of the second and the third blasting zones calculated for the specific conditions of the mine. The purpose of such intermediate row was to create a preliminary stress to improve the final block fragmentation.

After the changes in the blast design, in order to test its effect, limited amount of experimental blasts were carried out in the open pit with the fragmentation analysis of the crushed ore determined immediately after the blasts, at the block in the open pit using photos with the planimetric method of measurements.

As the result, the fragmentation analysis the crushed ore using standard blast design has shown that the amount of pieces of ore up to 300 mm in size averaged 48%, while the fragmentation with the proposed technology has shown that the amount of the same size pieces averaged at 73%, which meant that the fragmentation has improved by approximately 25%, which exceeded the expected results.

6 Conclusions

There is a new technology proposed to improve the efficiency of the fragmentation of rock during the drilling and blasting process in the open pit mines, which considers several important factors of blasting, like:

– zones of blasting;
– charge diameters;
– delays;
– other blast design parameters;
– properties of rock;
– geological and technical conditions of the specific mine.

In order to create an initial stress on the mining block intended for fragmentation, the following technology has been proposed:

– an additional row of charged holes with a certain spacing should be drilled in between the existing rows;
– the holes should be loaded so that the blasting power of them does not exceed the ultimate strength of the rocks to be crushed;
– these additional holes should be blasted first;

– blasting of the subsequent rows of holes must be carried out taking into account the level of the initial stress of the rock mass, which can be adjusted by the interval of deceleration of blasting depending on the physical and mechanical properties of the rock mass and the radiuses of the blasting zones;

– for the conditions of the "Belaya Gorka" site, the delay interval should be taken as 32 ms, for any other conditions the delay should be recalculated.

Once the intermediate row is blasted, the created by it elastic waves create an initial stress and open and closed cracks, but at the same time do not break the rock. Further, blasting of the first row of blast holes must be performed at the moment, when the wave of the blasted row of intermediate holes passes the first row of blast holes and creates an initial preliminary stress. In order to match the timing a delay time should be calculated. The effect obtained with such blast delay will provide interference of stress waves, which will facilitate their action and increase the effect of fragmentation in the block.

Approximate increase in the works required during the drilling and blasting process due to the addition of an intermediate row of blast holes is 15 to 20%, while as the experimental blast has shown the improvement in the ore fragmentation can be expected at an approximate level of 25%. So, if we take into account that the works during the mining processes are normally cheaper than the works performed during the mechanical ore preparation and processing, we can assume that the additional mining costs will eventually give larger savings in the costs of the downstream processes. So, the results obtained justify the further continuation of the research in this area and a necessity in a wider experimental work with more semi-industrial blasts in the operating mines, in order to perform a calculation of the full economic effect that this technology can provide.

Application of membrane processes in mining and mineral processing

Marinela Panayotova[1,*] and *Vladko* Panayotov[1,2]

[1]University of Mining and Geology, 1700 Sofia, Bulgaria
[2]BAS - Technical Sciences, 1000 Sofia, Bulgaria

Abstract. Sustainable mining and mineral processing is of paramount importance for producing metals needed for our society development. Membrane processes are able to contribute to the comprehensive extraction of metals from mined ores, while at the same time decrease the amounts of used water and reagents and ensure discharge to the environment of wastewater meeting the legislation requirements. Membrane-based technologies are still underused in metals obtaining although their development and price have made their application affordable. The paper presents in brief membrane processes and displays examples of their application in various areas of mining and mineral processing, such as coping with acid mine drainage and mine influenced water, recovery of metals, reagents and water in hydrometallurgy, recovery of lithium from brines, and treatment of wastewater. Emphasis is placed on pressure driven membrane processes, as well as on the very recent studies in the area. Advantages of membrane processes application in mining and mineral processing are pointed out as well as constrains to be overcome.

1 Introduction

The sustainable development of our society and our normal life needs metals - ferrous, nonferrous and minor. For the present, all metals can be ensured in required amounts only by the "chain" mining - extractive metallurgy (mineral processing, hydrometallurgy, pyrometallurgy and electrometallurgy).

Ores extraction by mining and metals extraction by mineral processing and/or hydrometallurgy are related with generation and /or use of different aqueous streams. When sulphide minerals, such as pyrite are disturbed by mining activities and exposed to oxygen and water chemical reactions take place - finally leading to formation of acidic water containing sulphates and ions of various metals in elevated concentrations, i.e. the so called acid mine drainage (AMD) is formed. When it is not treated, the AMD can result in a considerable pollution to both soil and groundwater [1].

Membrane technologies have been and are being studied for removing and concentrating different metals from AMD [2-5].

Generally, flotation is most effectively carried out with clean water. Changes in water quality are unwanted because this could affect the reagent regimes, finally resulting in compromise of the flotation performance. It is known that water quality impacts the flotation results and the following negative effects can be observed: loss of separation efficiency, loss of recovery, loss of concentrate grade, contamination of products [6]. At the same time the minerals industry is being requested to save freshwater by using recycled water and to minimize the discharge of wastewater into the environment. Since the flotation efficiency can be affected by the water quality, different approached have been and are being developed to cope with the problem. Among them membrane technologies are being studied to remove metal ions and improve the quality of water used in flotation [7].

Nowadays the shortage of many metals necessary for the modern economies, in combination with the increasing demand and the need to use low-grade ores, requires more efficient technologies for metals extraction. Hydrometallurgy plays a key role in processing and recovery of metals from challenging raw materials. Traditionally hydrometallurgical flowsheet includes i) ores leaching, ii) purification of the pregnant leach solution (PLS) by solvent extraction followed by stripping or by ion exchange followed by elution, and iii) metal recovery - where in many cases electrowinning is applied. In the latter case use of membrane technologies to pre-concentrate PLS is regarded recently as an way for lowering the energy consumption, enhancing the recovery of valuable metals and ensuring high recovery of reagents and fresh water [8].

Lithium (Li) is a very important metal in the production of rechargeable batteries, ceramics and glass, as well as lubricating greases. It is used in metallurgy (as casting additive, flux and alloying element) and in many other industries. Lithium can be extracted from either hard rock minerals and brines. Salt brines represent the most abundant lithium sources. They comprise approximately 60% of all known lithium deposits [9]. In the recent 10-15 years extensive work has been carried out to improve

Li recovery from brines by applying membrane technologies.

Membrane technologies have been and are being widely studied and applied to recover valuable metals from wastewater from mineral processing and extractive metallurgy while at the same time ensuring high quality of treated water. Even more, they may be applied also to leachates from mining waste.

Figure 1 presents a summary of the possible applications of membrane technologies in metals extraction.

Membrane technologies have been existing for around 50 years, but they are still not widely used in the general mining industry. That is why this paper aims at shedding some light on the opportunities presented by the membrane processes for more profound use of resources and sustainable production of metals, with an emphasis on the recent (3-4) years.

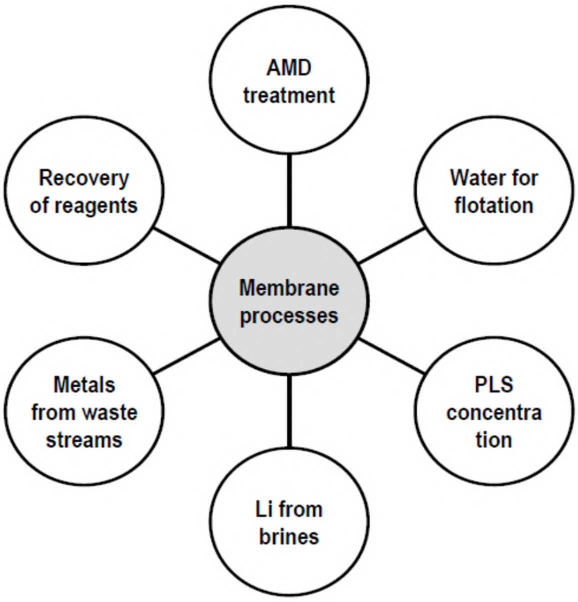

Fig. 1. Possible applications of membrane technologies in metals extraction

2 Membrane technologies in brief

Membranes are semi-permeable structures or films of materials that allow only certain species or substances to pass and prevent passage of others.

Different forces can drive substances to pass trough membrane - Table 1 [10].

Although there are some studies devoted to application of emulsion liquid membranes and supported liquid membranes techniques for extraction and recovery of metals from liquids (wastewater, waste liquids) the works on these applications are not so many and they are dealing with specific cases of extraction [13, 14].

Membrane distillation that can operate at low temperatures (60-90°C) enables the use of waste heat and thus seems a promising technology [15].

Forward osmosis is considered also a promising technology since it does not require a pressure application.

Table 1. Membrane processes classification based to the driving force

Driving force	**Membrane process**
Pressure difference	Microfiltration - MF, Ultrafiltration - UF, Nanofiltration - NF, Reverse osmosis - RO
Electric potential difference	Electrodialysis - ED, membrane electrolysis - ME, (membrane) electro-deionization -EDI, membrane electrophoresis
Chemical potential difference	Pervaporation, Per-traction, Dialysis , Vapour permeation, Liquid membranes - LM, Forward osmosis - FO
Temperature difference	Membrane distillation - MD

However, both MD and FO are evaluated as emerging membrane-based technologies and still enough studies and data are absent on their application [16].

Electrodialysis has been studied as a method for recovering the reagents and metals from stripping solutions [17], separating and recovering lithium from brines [18-20] and even in the mineral extraction from deep see water [21]. However these applications are still in the study stage.

The most studied and used membrane techniques, including in mining, mineral processing and extractive metallurgy, are based on a pressure difference between membrane feed and permeate sides - Table 2.

PDMPs performance generally is evaluated according to the following characteristics:

- Trans-membrane flux (J_v) [m/s]:

$$J_v = V_p / S_m \text{ x } t_p) \tag{1}$$

where: V_p - the volume of permeate [m^3], S_m - the surface of the membrane in contact with the flux [m^2], t_p - the time [s]

- Solute passage P

$$P = C_p / C_f \tag{2}$$

where C_f is the solute concentration in the feed and C_p - its concentration in the permeate

- Solute rejection (retention), in %

$$R = (1–P) \times 100 = (1–C_p/C_f) \times 100 \tag{3}$$

- Selectivity coefficient

$$(\alpha_{1/2}) = P_1 / P_2 = [C_p/C_f]_1 / [C_p/C_f]_2 \tag{4}$$

When retentate is concentrated to a small volume, the volume concentration factor (VCF) is determined

$$VCF = V_f / Vr \tag{5}$$

where V_f is the volume of the feed at the start of filtration and V_r is the retentate (concentrate) volume.

- Recovery

Table 2. Pressure driven membrane processes (PDMPs) [1, 10-12]

Process	Microfiltration	Ultrafiltration	Nanofiltration	Reverse osmosis
Membrane material[1]	CC, PP, PS, PVDF, CA	CC, PS, PVDF, CA, TFC[2]	CA, PVDF, TFC	CA, TFC
Membrane structure	porous, symmetric or asymmetric	microporous, asymmetric	tight porous asymmetric, thing film composite	dense, semi- porous, asymmetric
Retained diameter, μm	0,1 -10	0,01 - 0,1	0,001 - 0,01	< 0,001
MWCO[3], kilo Dalton	100 - 500	20 - 150	2 - 20	0,2 - 2
Operating pressure, bar	< 2	< 10	< 35	< 75
Separation mechanism	size exclusion	size exclusion	combination of size exclusion and solution diffusion	solution diffusion[4]
Permeate flux	high	high	medium	low
Usual module configuration[5]	tubular, hollow fiber	tubular, hollow fiber, spiral wound, plate-and-frame	tubular, spiral wound, hollow fiber	tubular, spiral wound, plate-and-frame
Examples of rejection	bacteria, micro-particles, fat, oil, grease, colloids	macromolecules - proteins, pigments, polysaccharides, detergents, viruses	high molecular weight compounds, polyvalent ions	high and low molecular weight compounds, poly- and monovalent ions

[1] CC - ceramic, PP - polypropylene, PS - polysulfonic, PVDF - polyvinilidene fluoride, CA - cellulose acetate, TFC - thin film composite membrane
[2] The RO and NF membrane presently of choice worldwide is the polyamide TFC. TFC membranes, composed of a strong asymmetric support membrane and a thin dense polyamide toplayer, have a higher permeability and can be used at higher temperatures at a broader pH range, compared to the others. Cellulose acetate membranes are chlorine resistant while TFC membranes have low resistance to chlorine.
[3] Molecular weight cut off range
[4] Solutes dissolve in the membrane material, then diffuse through it due to the concentration gradient. The separation is based on the differences in the solubilities of the solutes in the membrane and the different diffusion rates.
[5] There are four membrane configuration types for treatment systems: plate-and-frame (flat membranes sandwiched between membrane support plates which are arranged in stacks), spiral wound (flat sheet membranes separated by spacer screens and wrapped around a central core of a perforated collecting tube), hollow fiber, and tubular.

$$\text{Recovery, \%} = m_{P,end} / m_{F,\ ini} \tag{6}$$

where - $m_{P,end}$ - permeate mass at the end of the experiment, $m_{F,\ ini}$ - feed mass at the beginning of the experiment.

The permeate flux in membrane separation process, which determines its productivity, depends on the properties of the membrane, properties of the feed solution, trans-membrane-pressure, solute mass transfer coefficient (which influences the concentration polarization), membrane fouling.

The main factors influencing the selectivity and permeability of PDMPs are the pressure applied over the treated water (working pressure), the temperature and acidity of the treated water, the concentration and nature of the salts dissolved in the treated water.

The concentration polarisation and the fouling are the main factors affecting membrane performance. Concentration polarisation is the observed differential solute concentration between membrane surface and bulk stream. It is reversibly influenced by operation parameters. The fouling is formation of deposits on the membrane surface. It is irreversibly influenced by operation parameters.

3 Membrane technologies for treating AMD and mine influenced water

The high concentrations of sulfate ions and metals in AMD pose a severe risk to the environment.

Most often lime is added to AMD to raise its pH and precipitate the dissolved toxic harmful metals. However, the sludge produced by this process has no economic value and has to be disposed of, covering large areas of land. Acid mine drainage can be effectively processed and made satisfactory for discharge using membrane technology.

Studies on membrane processes application for treating AMD commenced at the 90-ties of the previous century with an emphasis mainly on RO.

Probably one of the earliest applications of membrane technologies was at Cananea de Mexicana where a full-scale RO - based plant was installed in 1997 to treat AMD - with copper recovery directly from concentrate - thus the process was paid back within 6 months [22].

NF and RO (single pass units) were applied successfully at the Kennecott Utah Copper's Bingham Canyon Mine Water Treatment Plant, now property of Rio Tinto Group, to treat AMD (pH 2,9 - 3,4, SO_4^{2-} - 73,8 g/L, Mg - 9,9 g/L, Al - 5,96 g/ L, and Ca, Cu, Fe, Mn, Zn - in the range of 0,150 - 0,599 g/L, TDS - 92 g/L) and contaminated groundwater. The solute retention for all pollutants was higher than 97 %. The main encountered problem was gypsum scaling [23].

Zhong and co-authors tested commercial polyamide ultra-low pressure reverse osmosis (ULPRO) and nanofiltration (NF) membranes for their ability to remove heavy metal ions from AMD. Rejections achieved were 97 % and 95 % respectively pointing at the possibility to recover metals from the concentrate obtained. In addition ULPRO removed also a major part of the dissolved monovalent ions thus decreasing the total water conductivity by 96% and rendering the treated water suitable for irrigation purposes [24].

Results from studies and applications of RO, ED, NF and UF for the treatment of AMD and mine influenced water (MIW), carried out till 2008, are comprehensively presented and discussed by Mortazavi [25].

A group of scientists at Freiberg University of Mining and Technology studied (2008 - 2010) the applicability of different RO and NF membranes for treating AMD. Experiments were carried out at two different pressures of 20 and 30 bar and at two different concentration levels in order to resemble the concentration range of actual AMD found in the mining industry. The results showed that NF membranes (NF99, DK, GE) successfully treated AMD, the heavy metals rejection was > 98% at higher fluxes and at lower pressure (consequently energy consumption) compared to RO. The DK membrane performed in the best way since it showed the highest rejection even at low studied pressure (20 bar) and high AMD concentration. The treatment has also been successfully conducted on a large scale in order to check its applicability at a commercial scale [3, 26, 27].

In 2010 the Interstate Technology and Regulatory Council (ITRC) at the Environmental Research Institute of the States announced that any one of the pressure driven membrane processes can be implemented to treat MIW, including surface and ground water [12]. According to ITRC the treatment goal(s) determine the process selection. The application of a given PDMPs generally depends on the: a) water quality requirements for the permeate (i.e., product water), b) location and source of water needing treatment, c) availability of utilities, d) options to dispose concentrates (retentate), e) quality of the water to be treated. Actually RO was successfully used to treat MIW rich in sulfates and TDS to achieve drinking water standards [28].

The EMalahleni water treatment plant (South Africa) was a solution for treating the coal mining industry influenced water in a reclamation project. AMD was collected from 3 mining sites, neutralized by lime addition which removed iron, magnesium and aluminium. After the clarification water was treated with UF and RO to produce potable quality water. The membrane separation step was repeated 3 times to maximize water recovery and minimize the concentrate volume. The feed water contained mainly calcium, magnesium and sulphate, with a small concentration of monovalent ions (sodium, chloride and potassium), and iron, manganese and aluminium [2, 29].

Dow NF 270 polyamide thin film and a TriSep TS 80 polyamide thin film nanofiltration membranes were studied for their ability to remove and concentrate ionic species from MIW in wide range of pH values of the polluted water [30]. The study proved that NF can be successfully used to achieve metal recovery objectives and meet discharge standards.

A study was carried out with the aim to assess the applicability of RO and NF to treat AMD from gold mines, as well as the main operational conditions. The results pointed that the NF had a higher potential to treat the AMD than the RO, since NF ensures higher permeate flux and satisfactory solutes retention efficiency. The best results were obtained with NF270 membrane at feed pH of 5,5 where the maximum water recovery rate was 60%. The estimated capital cost of the UF-NF unit at an effluent volumetric flow rate of 15 m^3/h was US$ 131250,00, and the operational cost was 0,263 US$/$m^3$ of effluent [31].

A very recent study has been carried out at a pilot-scale level with real AMD in order to determine and estimate the operating conditions for using a commercial NF membrane (NF270) to recover water and concentrate copper, as well as to find how NF can be coupled with SX for the selective copper recovery [32]. The water was acidic (pH 3,5) with high conductivity (5510 μS/cm) and high concentrations of some pollutants, in g/L: 4,67 SO_4^{2-}, 0,53 Cu, 0,38 Al, 44,70 Zn, 72,0 Mn. The study has proved that the combined NF-SX technology achieved a high recovery of water and copper from AMD. Thus, freshwater consumption can be reduced and wastewater treatment costs can be decreased.

Since UF works on low operating pressure (consequently energy consumption) and at high water recovery, studies have been carried out to use this membrane process to treat AMD and MIW. However, a means had to be found to modify the pollutants so that they could be retained by the larger pores of UF membranes. Here came to aid application of surfactants and polymers and micellar enhanced ultrafiltration (MEUF) and polymer enhanced ultrafiltration (PEUF**)** were proposed. PEUF is based on use of water-soluble polymer to complex metallic ions. The formed complexes possess a higher molecular weight than the MWCO of the membrane. The complex is retained by the UF membrane. Further, the retentate can be treated to recover metallic ions and polymeric agent for reuse. The polymers used (polyacrylic acid, polyethyleneimine, diethylaminoethyl cellulose and humic acid) achieved selective separation and high recovery of heavy metals with low energy requirements [33].

The MEUF is based on the use of a surfactant in the feed stream of the UF process. Dissolved ions which are intended to be separated are attracted by oppositely charged surfactant molecules. They attach to the surface of a micelle formed when the concentration of the surfactant exceeds the critical micelle concentration. Thus formed large ion-micelle complexes can be retained by the ultrafiltration membrane. Ions that are not attached to the surface of a micelle can penetrate through the membrane pores because of their small size. A drawback of MEUF is that it can cause secondary pollution to the environment if the used surfactants are leaked to the permeate. That is why, biosurfactants have been developed [15]. MEUF was successfully applied at pilot level to remove Cd and Cu from phosphorous rich real wastewaters [34].

Very recently a combination of FO and RO processes was proposed for treatment of mining wastewater [5]. Results from a pilot scale FO-RO (with a capacity of 1 m^3/day) pointed that this process could offer reduction in use of energy, chemicals, and piping infrastructure.

4 Membrane technologies for PLS concentration

Mainly gold and copper mines have invested in membrane systems to concentrate their PLS **[4]**.

In the early 90-ties of the previous century HW Process Technologies, Inc. installed at Freeport McMoran Phelps-Dodge Rod Mill El Paso one NF and two RO systems to treat H_2SO_4-based Cu-bearing PLS from heap leaching in order to increase the feed copper concentration to the SX/EW plant, reuse the permeate from the second RO system as rinse water, while the concentrate from the 1st RO system is passed also through a NF system. The NF concentrate was directed to copper refinery, while NF permeate was sent to Cu dissolving. In this way a Zero-Liquid (waste)-Discharge was achieved [22].

In 1999 the same company obtained an US patent for method for separating gold and/or silver from copper or other contaminant metals in which a NF membrane is used to form a retentate containing most of the multivalent metal cyanide complexes and a permeate, containing most of the precious metal cyanide complexes [35]. In next stages the precious metal(s) can be recovered from the permeate and the other valuable but non-precious metals - from the retentate where they present as multivalent metal cyanide complexes.

Minera Yanacocha is the largest gold producer in South America. Its mining and processing operations are in the Andes Mountains at height in the range 3500 - 4100 meters. The gold is extracted by heap leaching with diluted cyanide solution (30 - 50 mg/L free cyanide). Seven RO modules are installed (initial installation in 2003) at Yanacocha complex (250 m^3/h each one) and five excess water treatment plants, two carbon plants for recovering precious metals, and two Merrill Crowe processing plants [4]. During the rainy season, the PLS is being diluted and RO plants are used to dewater the PLS making the Merrill-Crowe gold extraction process more effective. Additional RO plants are installed to remove the cyanide and metals left and to allow the permeate water to be discharged and the concentrate to be returned to the extraction process. At the same time chlorine consumption (for cyanide destruction) is reduced by 75% and overall operating cost is 70% less than that of a conventional precipitation plant [22].

Because of the harmful impact of copper-cyanide complexes on the gold extraction process, the use of NF for separating $Au(CN)_2^-$ from $Cu(CN)_3^{2-}$ has been studied. Soldenhoff and co-authors reviewed some patented NF processes for gold processing designed to ensure separation of $Au(CN)_2^-$ from $Cu(CN)_3^{2-}$ in copper-rich cyanide solutions [36]. This separation can be realized by treating either the PLS from cyanide leaching operations or the loaded eluate from activated carbon extraction.

Treatment of copper-gold cyanide PLS from heap leaching where it is fractionated into a small, 1/10th, volume copper concentrated stream and a large, 9/10th, volume gold-bearing stream has been proposed [37]. The copper stream is processed further by sulfide-acid-re-neutralization-treatment to recover copper and return cyanide back to the process. The gold-(or gold-silver) permeate stream is processed to recover gold and the cyanide (concentrated by a membrane process from the barren solution) can be returned to the leaching. Thus both permeates and concentrates from the applied membrane processes provide added value.

Studies have been conducted also on membrane processes application to PLS from a pressure-oxidation (POX) of refractory gold ores [38, 39]. POX represents a hydrometallurgical oxidation of concentrated ore pulp under high pressure (20 bar) and temperature (135–200 ºC). During the pressure oxidation process, the sulfide in the host mineral matrix is oxidized by oxygen, thus producing soluble metal sulfates and sulfuric acid. In this way, the gold originally occluded in the sulfide minerals is completely released, allowing further high gold recovery by cyanide leaching. POX is efficient process for refractory gold ores but it generates a large volume of liquid effluents, characterized by high acidity and substantial metal content, and some of metals (Cu, Co and Ni) are of great economic value. The aim was to concentrate metals, and recover acid and water by applying combination of UF, NF and RO. The UF process is used as a pretreatment to avoid presence of suspended solids in the feed to NF system. NF membrane concentrates Cu, Co and Ni. An average concentration factor of 2 was observed for metals in the NF retentate. This concentration was favorable to subsequent recovery processes of metals (Co, Ni and Cu). The NF permeate (a metals-free solution with a low concentration of acid) is passed to the RO stage. There the acid is concentrated in RO retentate (with 2,5 times higher concentration of the H_2SO_4 and low impurity content - totally 0,58 mg/L) and could be recirculated to control acidity in the POX process. The RO permeate was water with quality for industrial reuse in the company. The best performance at a pilot-scale operation was while operating at recovery rate of 90%, 40–50%, and 50% for UF, NF, and RO, correspondingly. The total estimated cost of the proposed treatment was US$ 1,137/m^3 of effluent, including the neutralisation of UF and NF concentrates. A long-term work in a mining company validated suitability of the proposed treatment scheme. The same working group conducted further studies to find the most chemically stable membranes in order to increase the process sustainability [40]. Commercially available NF membranes (NF90, NF270, MPF34, DK, Duracid) and RO membranes (BW30, LP, TFC-HR, XN45, and SG) were assessed in terms of key performance parameters. The DK (as NF) and SG (as RO) membrane showed the highest capability for application in POX effluent treatment.

Application of membrane process has been studied and proposed also for recovering nickel from spent nickel electrolyte after electrowinning of Ni from purified PLS of the base metal refinery in the PGM cycle (Bushveld Complex, South Africa) [41]. Energy costs limit the recovery of nickel in the electrowinning unit to 50% thus making the recycling of the spent nickel electrolyte significant for cost-effective nickel production. In the "classical scheme" four units are necessary for nickel concentration and sending back to the cycle. They are replaced by one NF unit. The retentate stream where nickel is concentrated is recycled back to the nickel electrowinning cells together with the sodium sulphate to ensure the needed conductivity while the permeate is recycled back to the leaching circuit in order to reduce the overall sulphuric acid consumption of the base metal refinery.

Very recently a study has presented a promising process chain for the separation of Ge and Re from an acidic multicomponent PLS obtained by bioleaching [42]. The proposed treatment chain includes consecutively MF, NF, and RO. For the MF pretreatment rotating ceramic and polymeric (MV020) membrane filters are proposed. Over 99% of the leached sludge particles are retained and can be recycled for bioleaching as leaching bacteria are still present. In the further step the sterile solution is passed to NF system. With NF99HF it is possible to remove all cations (Co^{2+}, Cu^{2+}, Fe^{3+}, Zn^{2+}) at retention ≥ 99% and Mo at retention > 97%. Concentrate is sent to the refining stage while the permeate stream is transferred to the next RO step (with RO90 membrane). There the Ge is concentrated in the retentate while Re passes to permeate. Both high tech elements can be further extracted from the corresponding streams by solvent extraction or adsorption.

5 Membrane technologies in obtaining lithium from brines

According to some estimates, nowadays 2/3 of the worldwide produced lithium is extracted from brines. This technology evaporates normally half a million litres of brine per ton of lithium carbonate. The process is chemicals intensive, extremely slow, and delivers large volumes of waste [43]. Methods have been searched for to speed the extraction and mitigate its environmental impact, including recovering at least some part of the water in brine as pure water.

Brines are highly saline solutions, containing typically large amounts of Na^+, and lower concentrations of Li^+, K^+, Mg^{2+}, and Ca^{2+}. The equivalent anions generally are mainly Cl^- with minor amounts of SO_4^{2-}, HCO_3^- and borates. Lithium concentration is low (in the range 0,3 - 1,5 %), concentrations of the other metals are high, and the chemical properties of the presenting Na^+ and K^+ are similar to those of Li^+. Consequently efforts to directly precipitate Li^+ salts from brine lead also to precipitation of large amounts of Na^+ and K^+ salts [44]. In addition, presence of Mg in high concentrations is also detrimental, since it possesses greater affinity to lime as compared to lithium, leading to inefficiency in lime precipitation of Li and also hinders the ED separation of Li [9].

Consequently, it is essential to find process for efficient separation and recovery of lithium from brine sources. NF and ME are the membrane processes mainly used in this application.

NF and low pressure reverse osmosis (LPRO) have been studied for their ability to separate lithium from salt lake brines with an emphasis on Mg^{2+}/Li^+ separation [45]. The results pointed that NF90 membrane was more efficient for Li^+ separation from a diluted brine because of its higher hydraulic permeability, lower critical pressure, its high rejection of Mg^{2+} (approximately 100 %), low rejection of Li (only 15 %), its higher selectivity between monovalent ions (40 %) obtained at lower operating pressure (below 15 bar) and its lower roughness showing decreased predisposition to fouling. However, the further step aimed to separate from the obtained permeate Li^+ and Na^+ by using the NF90 was not successful and dialysis at zero pressure was used to ensure the separation. Other authors also pointed that NF is suitable process for separation of Li^+ and Mg^{2+} from brines [46, 47].

Membrane electrolysis combined with crystallization is proposed as a new technology for lithium carbonate production from lithium-rich brines [44, 48, 49]. In the first stage brine is introduced in a membrane electrolyzer where anodic and cathodic departments are separated by anion exchange membrane. Water reduction increases the pH of the catholyte, and there Mg^{2+} and Ca^{2+}, migrated due to the applied voltage, are removed as $Mg(OH)_2$ and $Ca(OH)_2$. In the second stage brine, from which Mg^{2+} and Ca^{2+} are removed, is introduced in the middle compartment of a three-compartment water electrolyzer. Anodic and cathodic compartments are separated from the middle compartment by anion-exchange (AEM) and cation-exchange (CEM) membranes correspondingly. Monovalent cations (left in the brine after the first stage) migrate from the middle compartment through a cation exchange membrane to the cathodic compartment where water electrolysis leads to alkalinisation. It is found that under the experimental conditions applied, the ionic migration rate across the CEM decreased in the order $Na^+ > K^+ > Li^+$. A side-crystallizer is attached to the cathodic compartment and Na^+ is recovered as $NaHCO_3$ by introduction of CO_2 in the system. At heating the bicarbonate solution, the bicarbonate is converted to carbonate solid samples. Na_2CO_3 with a purity of 99.5% of was obtained from real brine samples. Thus the solution is depleted in Na^+ ions and it is more suitable for Li_2CO_3 recovery in a successive stage. This solution is introduced (in the 3rd stage) into the middle of another three-compartment water electrolyzer, similar to the one applied in the 2nd stage. Since the water is deprived of Na^+ ions, mainly Li^+ ions pass to the cathodic compartment, where, due to the alkalization caused by the electrolysis and introduction of CO_2, Li_2CO_3 (with a purity of 93,8 wt. %) is precipitated in a side-crystallizer, attached to the cathodic compartment. The method proposed recovers fresh water as a by-product (around 90 % of the initial volume).

More on the advantages and challenges of the membrane-based technologies applied to the lithium recovery from brines till the middle of 2019 can be found in the work of Li and coauthors [50].

Studies development in that area hinted to the idea that an integrated membrane separation process could be a potent alternative to conventional Li recovery methods. An integrated membrane process combining NF and MD was studied for the enrichment of Li from simulated salt lake brine [9]. NF90 and NF270 NF membranes were used in experiments. It has been found that under optimum operating conditions, the Mg/Li molar ratio changed from 10 to 0,19 when NF90 was used, and from 10 to 2,1 at NF270 use. The achieved concentration of Li from brine was 77 and 56% for NF90 and NF270 membranes respectively. Following NF treatments, the separated Li could be further concentrated (by up to 80 %) by means of direct contact MD system. Park and co-authors [51] also confirmed the ability of the combination NF - MD to recover Li from low concentration lithium brine, as they stresses, at "one-tenth of capital cost, process time, and foot-print of the conventional process". The cost can be decreased further by using the waste heat from the industrial plants and solar energy.

Very recently a comprehensive technology for preparation of Li_2CO_3, has been proposed [52]. It includes electrochemical intercalation-deintercalation, nanofiltration, reverse osmosis, evaporation, and precipitation. In the beginning the electrochemical intercalation-deintercalation method is used to ensure maximum separation of magnesium and lithium, i.e. to obtain a low mass ratio Mg/Li. The Mg/Li ratio decreased from 58,5 in the brine to 0,93 in the produced lithium-containing anolyte. Further, multivalent ions (e.g., Mg^{2+}, Ca^{2+}, and SO_4^{2-}-) are removed from the obtained anolyte via the NF method. Then NF permeate is concentrated by RO. The next step uses evaporation to increase further the lithium concentration. Finally Li_2CO_3 is precipitated by Na_2CO_3 addition. By the proposed technology a direct recovery of lithium from the high Mg/Li brine to the produced Li_2CO_3 can come to 68,7%. When recycling is ensured for the most of the solutions in the system, the total recovery of lithium will be higher than 85%.

6 Membrane technologies for recovering reagents, metals and water from mining waste streams

Treatment of in-plant process effluents and wastewater streams are presented in this section.

Membrane processes have been applied for treating in-plant effluents in order to regenerate reagents and/or to separate valuable materials. An example is application of ED for recovery of HCl, zinc and iron contained in effluents from chloride hydrometallurgy [17]. The waste stream was with high concentration of hydrochloric acid and of metal anionic and cationic chloro-complexes. Initially selective membrane-based solvent extraction step was applied to separate in raffinate cationic iron from the stripping solution that contained the HCl together with anionic species of zinc. The stripping solution was passed to ED system where Zn was concentrated in concentrate and the latter was suitable for Zn electrowinning. HCl was recovered in diluate to be re-used in the leaching process.

Another example is recycling of H_2SO_4 from raffinate, generated during copper ore hydrometallurgical processing, by use of bipolar membrane electrodialysis (BMED) system [53]. The raffinate is highly acidic and contains Fe, Zn, Cu, Ni, Cr, Cd, As in high concentrations. The experiments showed that 85,9% of SO_4^{2-} that present in the raffinate could be recovered by the formation of H_2SO_4. The removal rates of other pollutants were, in %: iron - 99,3, zinc - 99,1, copper - 99,0, nickel 84,9%, chromium - 70,6, cadmium - 95,8%, and arsenic - 94,8.

In order to find a sustainable solution for fresh-water demand in mining sectors, MD was proposed to reclaim POX effluent [54]. Different operational conditions were studies and under the optimum ones (PTFE membrane with spacer, feed temperature - 60 ◦C, recirculation flow rate - 0,3 L/ min), the average distillate flux was 6,82 L/m^2 h and a permeate recovery rate was 33,91% at retention rates for metals > 95,7% and for the acid > 99,9%. The system was working 240 days without any deterioration of parameters, generating a permeate that can be used directly as recycled water in the plant. Since the temperature of the POX effluent is in the range 50 - 80 ◦C, the effluent can be introduced directly into MD system thus decreasing the energy demand for the effluent processing.

In general, RO is the major membrane process used by the developed countries to treat wastewater streams from mine sites, especially with the aim to achieve water quality meeting the legislation requirements permitting water discharge in natural water bodies. Most often the technology is applied for water polishing after other treatment processes and before discharge to the environment. For example Oceana Gold - Waihi (New Zeeland) applies RO since 2008 to remove pollutants, such as TDS, Se and As left after treating the wastewater by a conventional wastewater treatment plant using chemical precipitation and clarification [22]. The water is purified to a level of purity, far in excess of that required by regulators [55].

Many mines in Australia are using the RO technology as a post-treatment process for removing heavy metals and other toxic compounds from their wastewaters before water discharge to the environment [56-58]. However, membrane fouling appears as one of the biggest problems when RO is used in a harsh environment like as mining operations.

A study evaluated the performance of RO plant as a wastewater post-treatment process in mining operations in Victoria, Australia [56]. The data analysis points that the RO treatment significantly improves the quality of the final water before it is being discharged to surface waters. Considering average rejection efficiency for the entire evaluated period (01.01.2015 - 27.11.2018), the concentrations of antimony, arsenic, nickel, zinc and iron were reduced by 95 %, 66 %, 82 %, 48 % and 10 %, respectively in the RO permeate compared to the feed water. The turbidity and TDS decreased by 85 % and 96 %. However, the sporadic inefficiency of the pre-treatment system, led up to serious failures in RO plant, resulting in a non-compliance with local discharge licence in some days. The conclusion was that since RO membranes are very sensitive to fouling, availability of a reliable and extensive pre-treatment system is the most critical factor to guarantee good performance and high durability of membranes.

Legislative measures forced not only gold and copper mining companies but also coal-mining enterprises to search for solutions to minimize their saline wastewater. A study was carried out aimed at evaluating the performance of an integrated FO - RO system with three different actual coal mine waters from Australia, containing different concentrations of sulphates and silica that are usually related with scaling and fouling of membrane systems [59]. Studies have shown that the integrated system concentrated the mine water, recovering more than 80% of the mine water volume and producing treated water of dischargeable quality. It is found that the combination of FO with RO provided a better results than individual FO or RO. The FO unit performed as an effective pre-treatment system prior to RO and showed a potential to successfully replace conventional pre-treatment processes for RO.

7 Conclusions

Application of membrane-based processes in mining and mineral processing industry offers many potential benefits such as (a) Improved selective separation of valuable metals, (b) Water and reagents recovery for reuse in the production process, (c) Reduction of volumes requiring conventional treatments, such as lime neutralization and precipitation. This in its turn leads to decreased usage of reagents and reduced costs for disposal, (d) Release of wastewater aligned with stringent regulatory standards for water discharge to the environment and even production of water usable for industrial, agricultural, and domestic purposes, (e) Efficiently dealing with AMD and MIW.

All mentioned translates into smaller and more efficient plants with lower capital and operating costs, as well as decreased environmental negative impacts.

Flexible application of membrane based technologies, with relatively small footprint, compared to traditional technologies, can be ensured by nowadays developments in the area. While RO is still "classics" in the wastewater treatment, in in-process technology NF gains increasing attention, since RO and NF provide similar rejection performances for commodity metals and multi-valent ions and NF shows a higher flux at lower pressure, leading to lower capital investment, lower cost of operation and maintenance. MF and UF are considered as necessary and suitable pre-treatments to remove suspended solids prior NF and RO operations.

Among the barriers hindering the application of membrane-based processes in mining and mineral processing the following can be pointed out: (a) Still relatively high capital and operational costs, (b) Fouling and scaling of membranes, since the waters entering the membrane plant have a large amount of complex suspended and dissolved solids. Need of chemicals and pre-treatment to avoid the mentioned problems and to ensure feed solution with predictable quality, (c) Still some improvements in module design and process optimization are needed.

However, the developments of science an technology in the area of membranes and membrane technologies is going to mitigate these problems.

Hopefully, this paper will be useful in providing some information and basis for widening the application of membrane technologies in mining and mineral processing in order to render metals extraction more environmentally friendly and sustainable.

Abstract. A theoretical scheme of gas release from the coalbed under production by treatment workings has been developed. The sizes of zones of different intensity of gas release from the working thickness are set according to the characteristic points of muld shift of the earth's surface. Total amount of releasing gas is determined by the area of the developed space, over which there is an intensive movement of the mined coal. The formation of this area is associated with the development of cleaning operations within the boundaries of the excavation site and the speed of movement of the treatment face. During the development of the theoretical scheme, several assumptions were made, the validity of which was verified on the basis of experimental data obtained in the conditions of four mines at fifteen excavation sites. Coal seams with coals of grades G and A were worked out by them at a depth of 300-1195 m, the capacity of coal seams was 0.90-2.20 m, cleaning works were carried out at a depth of 300-1195 m, the length of the lavas was in the range of 74÷270 m. The monthly movement of the treatment faces and the amount of gas released during this period were taken into account for each excavation site. It is established that the relative gas release per unit area of the developed space remains a fairly constant value for some mining and geological conditions, if the total amount of gas is attributed to the area that determines the active movement of rocks over a moving treatment face. This allows you to use the previously obtained results of determining the categorical danger of mines by relative gas release per ton of coal production in terms of improving the forecast of gas release from the coalbed under production more efficiently.

1 Problem statement

In modern coal mines, the main source of gas emission is the undermined coal-bearing strata.

The relationship between the intensity of gas emission and the degree of was established several decades ago [1, 2]. The highest levels of gas emission are associated with sediments of the main roof [3] and the development of the underworked strata movement towards the earth's surface when removing waste rock. Methane emission into mine workings is possible only from the zone of underworked strata movement with a break in its continuity. In degassing wells, methane emission can also occur from lamination cavities at the contacts of rock layers with different strength properties [4].

In parallel with the influence of the underworked strata movement, the phenomenon of a decrease in the specific flow rate of methane into the stope was established with an increase in the intensity of mining of shallow coal seams [5].

The intensity of seam mining means the level of coal production and the corresponding movement of the mine face. For the safe mining of gas-bearing coal seams, it is necessary to know the mechanism of formation of methane release from the underworked coal-bearing strata. Until now, there are practically no scientific research works in which the intensity of coal seam mining (the level of coal production or the rate of mine face movement), the development of undermining and gas release from undermined sources are considered together. Research in this direction is highly relevant.

2 Purpose, idea and research methodology

The objective of the study is to develop a scheme for the influence of mine faces on the formation of zones of active movement of the undermined coal-bearing strata and the possible intensive emission of methane from them. Establish the factors that determine the gas emission in relation to its emission per unit area of the underworked area.

Idea. It is assumed that the amount of emitted gas depends on both the rate of movement of the mine face ($\upsilon_{оч}$), and the intensity of the movement of rocks above it and the degree of development of mining operations in the extraction area.

Methodology. It provides for the consideration of experimental data on methane emission in relation to the developed scheme of the influence of mine face on the formation of zones of active undermined coal-bearing strata movement and gas release from the undermined strata.

Results. The layout of the methane emission zones in the undermined coal-bearing strata was developed in accordance with the formation of a displacement trough on the earth's surface [3] and the degree of development of mining operations in the mining area (Fig. 1).

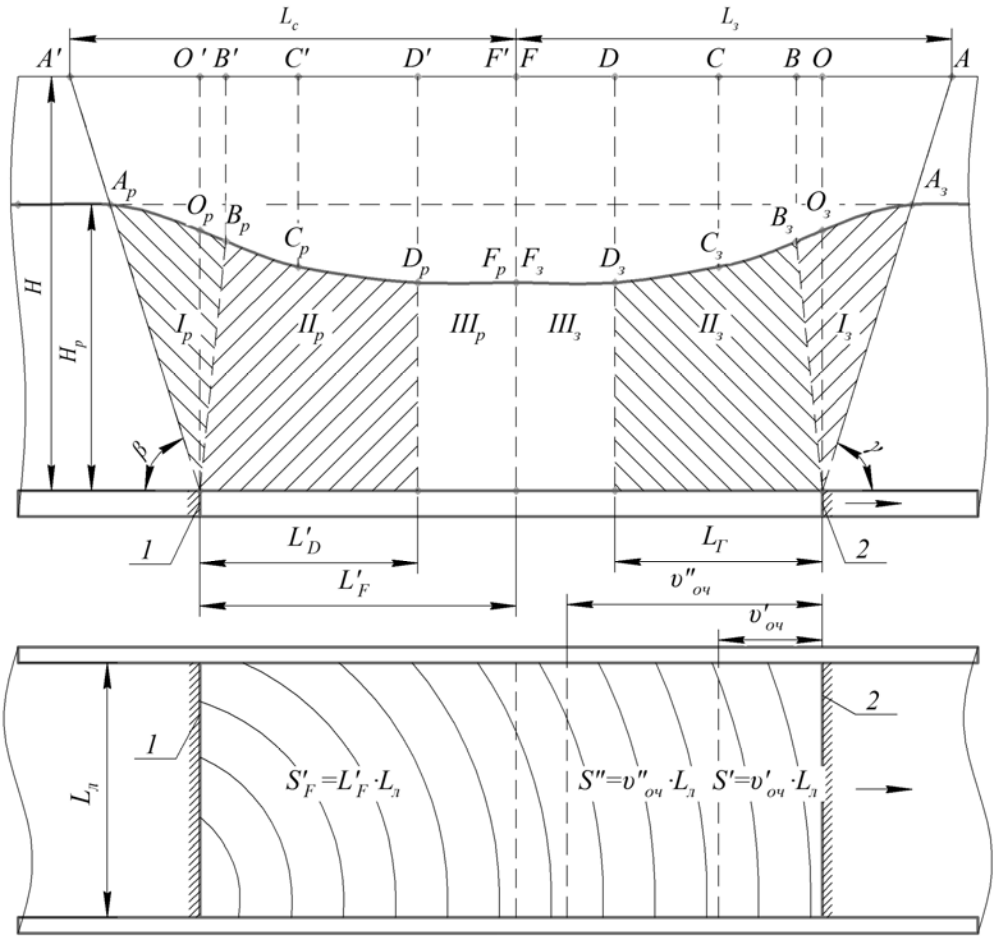

Fig. 1. Scheme of the location of gas emission zones in the undermined coal-bearing strata according to the formation of a displacement trough on the earth's surface (a) and the degree of development of cleaning work (b) in the excavation area: 1, 2 – respectively, the exposed surfaces of the seam of the cut mine and the clean face; 3 – earth surface; L_c, $L_д$ – respectively, stationary and dynamic semi-troughs; *A*, *O*, *B*, *C*, *D*, *F* and *A′*, *O′*, *B′*, *C′*, *D′*, *F′* – characteristic points of subsidence of the earth's surface of dynamic and stationary semi-troughs; A_p, B_p, C_p, D_p, F_p and $A_з$, $B_з$, $C_з$, $D_з$, $F_з$ – characteristic points of subsidence of a layer of undermined rocks at the edge (H_p) of a zone with a discontinuity, respectively above the open cut and the clean face; *H* – depth of cleaning works; $I_з$, $II_з$, $III_з$ and I_p, II_p, III_p – areas of possible gas enission, respectively, above the clean face and open pit; β, γ - boundary angles of influence of a working mine on the earth's surface; L'_D - the distance between the open pit and the clean face at which active gas emission occurs; L'_F - distance at which gas emission from the side of the cut furnace stops due to rock compaction; $L_Г$ - distance from the working face, at which active gas emission occurs from the undermined coal-bearing strata above the working face; $L_л$ – longwall length; S', S'' - the goaf, respectively, when moving the working face at a distance of $\upsilon'_{оч}$ and $\upsilon''_{оч}$; ⟶ - direction of the working face. movement.

3 Results

According to this scheme, a displacement trough is formed on the surface under the influence of cleaning works, which is divided into two semi-troughs. One of them, the stationary length L_c, is formed above the split mine (1). The second is a dynamic length $L_д$, it is formed as the clean face moves forward (2). These semi-troughs, according to the methods [3, 6, 7], can be divided into separate periods of their formation using characteristic points. Section $A'B'$ of the semi-trough of the earth's surface (the diagram shows a segment of straight line $A'B'$) corresponds to the initial period of the earth's surface displacement under the influence of a moving clean face. The most active earth's surface displacement occurs on the curve section $B_P\,D_P$, and at the point C_P the maximum subsidence rate is reached. At the point D_P, the end of the active stage occurs and the transition to damping of the processes of the earth's surface displacement occurs. At point F, the maximum subsidence is achieved and further advancement of the clean face has practically no effect on the processes of active movement of unmined rocks and the earth's surface.

Similarly, with different intensity, the undermined rocks move above the clean face in the coal-bearing strata. By analogy with the earth's surface, a subsidence semi-trough is formed in it with characteristic points $A_з$, $B_з$, $C_з$, $D_з$ and $F_з$. Insignificant gas emission from the rock stratum is possible from zone $I_з$, the dimensions of which are determined by the boundary angle and the position of the point $B_з$ in the undermined range. Point $B_з$ is located at a distance of H_p from the developed formation, which defines the boundary of the displacement zone of rocks with a break in their continuity. With the removal of the stope from the cut, H_p reaches a certain value, which remains constant as the extraction column is further worked out [8, 9, 10]. The most favorable conditions for intense gas emission appear in the zone ($II_з$) of active rock movement. The dimensions of this zone are determined by the section of the $B_з$ – $C_з$ – $D_з$ curve and the H_p parameter. Separate determination of gas emission from zones $I_з$ and $II_з$ experimentally in mine conditions is practically impossible due to the technical capabilities of modern measuring equipment. Based on the gas surveys in mine workings and measurements in degassing systems, it is possible to establish the total gas emission from zones $I_з$ and $II_з$, neglecting methane emission from zone $III_з$. The most accurate and accessible indicator characterizing the size of these zones is the area of the mined-out space $S_Г$. It can be determined by the product of the parameter $L_Г$ and the length of the $L_л$ longwall. The value of the parameter $L_Г$ is determined by the projections of points D and $D_з$. For coal mines of Donbass, the L_p parameter is approximately equal to 0,466 of the depth (H) of mining [3]. Based on the above scheme (Fig. 1), it follows that all the gas emission from the undermined strata (I_υ) when moving the clean face can be roughly attributed to the goaf area $S_Г = L_л \cdot L_Г$.

In production conditions, the value of the $L_Г$ parameter, as a rule, does not coincide with the monthly rate of movement of the clean face. If $\upsilon_{оч} < L_Г$, when determining the specific gas emission from the ratio, this indicator will be overestimated. Gas emission in fact refers to the goaf area of $L_л \cdot L_Г$, and it is referred, in some cases, to $S' = \upsilon'_{оч} \cdot L_л$.

It is extremely rare that the $\upsilon''_{оч}$values can exceed the $L_Г$ parameter, then $S'' = \upsilon''_{оч} \cdot L_л$ will exceed the $S_Г = L_л \cdot L_Г$ area and the specific gas emission per unit goaf area will be underestimated.

It can be assumed that, according to a similar scheme, gas emisiion occurs above the open cut from zones $I_з$ and $II_з$. Their sizes are also determined by the position of the characteristic points A_p, B_p, C_p, D_p and F_p in the underworked strata and the value of the H_p parameter.

When the clean face is removed from the open-cut mine at a distance of L'_D, zone II_p is largely degassed, since it was subjected to the most intense rock movement. Some gas emision is possible from the I_p zone, in which rock displacements were insignificant.

When the clean face is removed from the open-cut mine at a distance of L'_F, zones III_p and $III_з$ are more degassed. The rocks in these zones, before their compaction, successively went through all stages according to the intensity of their movement and, obviously, according to the activity of gas emission from underworked sources.

In the process of developing the scheme (Fig. 1), several assumptions were made that need to be verified and confirmed by experimental results. These include the assumption of the similarity of the gas emission processes from the undermined coal-bearing strata when the clean faces are removed from the split furnaces in the initial period of the excavation sections operation at a distance of L'_D (with the settlement of the main roof in zone II_p) and methane emission above the clean face, determined by the boundaries of zone $II_з$ and the goaf area $S_Г$, calculated using the parameter $L_Г$.

The analysis involved the results of the cleaning works development observations and gas emission at fifteen excavation areas of four mines. For these sites, in advance, considering the depth (H) of the cleaning works, the $L_Г$ parameter was determined [3]. For the conditions of the A.F. Zasyadko mine [11] (16th eastern longwall of the $m_3$seam) for a depth of H = 1195 m, the value of $L_Г$ is 547 m.

In the conditions of the 'Sukhodolskaya - Vostochnaya' mine, during the operation of the 12th bis and 24th eastern longwall of the $i_3$seam, the depths were 965 and 1016 m respectively, and they corresponded to $L_Г$ values of 450 and 474 m. For the D.F. Melnikov mine, the extraction area of the 1st northern longwall of the $\ell_6$seam was mined at a depth of 852 m, for which the parameter was 397 m. Mine in the name of the "Izvestia" newspaper mined an anthracite layer $\ell_2^в$at a depth of 300 m, and the calculated value of the $L_Г$ parameter was 140 m.

For each excavation site, monthly movements of the clean faces were pre-established and the amount of gas emission during this period was determined experimentally. After that, the movement of the clean faces ($L_{оч}$) was sequentially selected for a certain period (one or several months), starting from the moment of longwall operation in such a way that $L_{оч} \approx L_Г$. Then, for the selected values of $L_{оч}$, the goaf areas $S_Г = L_{оч} \cdot L_Г$ were found, which corresponded to gas emission when the clean faces moved to a distance of $L_{оч}$. We also took into account the period of longwall operation (t) when moving the faces to a distance of $L_{оч}$, the average gas emission per month and the specific methane emission $\frac{I_\upsilon}{S}$per m² of the goaf area when moving the clean faces at a distance of $L_{оч}$. This data is summarized in Table 1.

When the clean faces move in the initial period of exploitation of the extraction areas at a distance $L_{оч} \approx L_Г = L'_D$ (Fig. 1, Table 1), in most cases, the indicators of the amount of gas (I_υ), its average amount ($\bar{I}_1$) emitted in one month, as well as the specific gas emission from units of the goaf area $(\frac{I_\upsilon}{S_Г})$ were less in comparison with their subsequent values when moving the clean faces at a distance of $L_{оч}$. This is explained by the fact that intense gas emission from the undermined coal-bearing strata does not begin immediately after the introduction of the longwalls into exploitation, but occurs after the main roof has settled.

For example, in the conditions of the “Izvestia” mine, the sediment of the main roof occurred when removing clean face from cut workings at a distance of 80÷120 m [3]. At the same time, the peak values of methane emission when moving the clean faces on the L'_Dsection (Fig. 1, a), located closer to the open-cut working, were slightly higher than the gas emissions during their subsequent moves by the value of $L_Г$. The total amount of gas $I_v$emitted during the passage of the longwall sections $L_Г$ of the extraction pillars located far from the split furnaces, as a rule, exceeded this indicator during the operation of longwalls near the split workings.

* Note - removal of clean faces from cut workings at a distance of $L_{оч}$ in the period before the settlement of the main roof.

Such a ratio of indicators for gas emission in the areas $L_D^{'}$ and $L_Г$ indicates a different course of the processes of rock displacement and gas emission when clean faces are located in different parts of the extraction pillars.

We examined in more detail the cases when mining pillars in the areas $L_D^{'}$ and $L_Г$, when the indicators I_υ, $\bar{I}_1$ and $\frac{I_\upsilon}{S_Г}$ were quantitatively close to each other.

The D.F. Melnikov mine, during the operation of the 1st northern longwall of the $\ell_6$seam, the section of the pillar L_D'=$L_{оч}$= 408m near the split furnace was worked out for twelve months, and the subsequent section $L_Г$ = 409m after the settlement of the main roof - nine months (Table 1). During these periods, approximately the same amount of methane was emitted, respectively 2,8 and 2,7 mil m^3. In this case, with approximately the same areas of undermined stratum (89760 and 89980 m^2), practically the same amount of gas was emitted over different periods of time when a part of the extraction pillar was worked out on segments L_D' and $L_Г$. This indicates that the amount of methane emitted from the zone of active movement of underworked rocks depends on the time of degassing of the coal-bearing strata. The influence of the time factor on all indicators of gas emission I_υ, $\bar{I}_1$ и $\frac{I_\upsilon}{S_\Gamma}$)) is confirmed by the experimental results obtained during the refinement of the extraction pillar of the 1st northern longwall with a length of 392 m for thirty months. During this period, 5,3 mil m^3 of gas was released, because of which the $\frac{I_\upsilon}{S_\Gamma}$indicator also increased from 30,0 to 61,5 m^3/m^2 of methane (Table 1). The amount of methane emitted per month remained practically unchanged. After stopping the clean face (S_Γ=0), 0,5 mil m^3 of methane was emitted over eight months. The $\frac{I_\upsilon}{S_\Gamma}$ indicator must be determined according to the scheme (Fig. 1) from the $\frac{I_\upsilon}{L_\Gamma \cdot L_л} = \frac{0{,}5 \cdot 10^{-6}}{397 \cdot 220} = 5{,}7$$m^3/m^2$ ratio. After stopping the clean face, its movement is absent, which caused a decrease in the specific gas emission per unit of goaf area from 61,5 to 5,7 m^3/m^2. In this case, if the amount of emitted gas is related to the area corresponding to the monthly movement of the clean face (S_υ=0), then the $\frac{I_\upsilon}{S_\upsilon}$ indicator tends to infinity and it has no practical value. A similar mistake is made by the methodology of regulatory framework when determining the hazardousness of mines, when the amount of emitted gas is attributed to coal production per month. In its absence, the gas content of the mine seemingly tends to infinity. The absolute gas emission when the clean face is stopped depends on the the location of sources in the undermined coal-bearing strata, which are no longer associated with coal mining [13, 14].

On the site of the 8th western longwall of the $\ell_2^в$ seam of the "Izvestia" mine part of the extraction column L_D'=$L_{оч}$=151m was worked out for three months, and the next – $L_Г$ =131m for one month. During the exploitation of the mining area, 1,4 and 1,2 mil m^3 of methane was emitted in the corresponding periods. Indicators $\bar{I}_1$ and $\frac{I_\upsilon}{S_\Gamma}$ in the corresponding periods were equal to 0,5 and 1,2 million m3 and 43,1 and 42,6 m^3/m^2. In this case, with the same $\frac{I_\upsilon}{S_\Gamma}$ indicator, the average amount of gas emitted in one month significantly differed. Such a ratio of parameters in this case can be explained by the incomplete development of rock displacement processes at the initial stage of seam development at $L_{оч}$= 151m. After stopping the longwall, 0,5 mil m^3 of gas was emitted in two months. For this case, $\frac{I_\upsilon}{S_Г} = \frac{0{,}5 \cdot 10^{-6}}{140 \cdot 215} = 16{,}6$ m^3/m^2. This indicates a decrease in the specific gas emission per unit of goat area in the absence of coal mining for a certain period.

After stopping the 9th western longwall, 0,3 million m^3 of methane was emitted in four months, and the specific gas emission during this period was 8,6 m^3/m^2. This confirms the validity of the fact that when calculating the specific gas emission per unit of goaf area, the amount of emitted gas I_v must be related to the $S_Г$area that determines the active zone of rock displacement.

If the rate of clean face movement ($\upsilon_{оч}$) is approximately equal to the calculated value of the size of the zone of active displacement of rocks ($L_Г$) (Fig. 1), then it can be assumed that the values of specific methane emission per unit goaf area ($\frac{I_\upsilon}{S_\upsilon}$ and $\frac{I_\upsilon}{S_\Gamma}$) will slightly differ from each other. The closeness of the $\frac{I_\upsilon}{S_\upsilon}$ and $\frac{I_\upsilon}{S_Г}$parameters in this case also indirectly indicates the reliability of determining $L_Г$ by a calculation method.

Of the considered excavation areas, working out different seams, only in the conditions of the "Izvestia" mine for individual mining areas, in some cases, the speed of clean faces ($\upsilon_{оч}$) was close to the indicator $L_Г$ =140m. The $L_Г$ determination accuracy is about 20%. In this case, the $L_Г$ value is 140÷28m and should be in the range 112÷168m.

For six excavation areas, where there were cases of approximate equality $L_Г \approx \upsilon_{оч}$, we made samples according to the rate of clean faces movement in the indicated interval (112÷168m) and the corresponding amount of released gas ($I_{\upsilon_{оч}}$) and area ($S_{\upsilon_{оч}}$ and S_Γ) of worked-out spaces (Table 2). The graphs of the experimentally determined $\frac{I_{\upsilon_{оч}}}{S_Г}$ and $\frac{I_{\upsilon_{оч}}}{S_{\upsilon_{оч}}}$ values practically coincided with the bisector (1) of the coordinate grid (Fig. 2).

This is evidenced by the closeness of the regression coefficient to unity of the averaging straight line (2) and the high value of the correlation coefficient (r=0,97). The established facts indicate that in order to reliably determine the specific gas emission from a unit area of the goaf, it is necessary to take into account the zones of active movement of underworked rocks.

4 Conclusions

Conducted theoretical and experimental studies of gas emission from the undermined coal-bearing stratum by workings made it possible to draw the following conclusions:

- the developed theoretical scheme for the joint formation of zones of the undermined coal-bearing stratum active movement and intense gas emission made it possible, on the basis of experimental data, to establish a part of the goaf area, which determines the amount of methane emitted from the sources;

Table 2. Information on gas emission at the rates of clean faces ($\upsilon_{оч}$) is close to the size of the $L_Г$ zone of active movement of rocks in the conditions of the "Izvestia" mine.

Abstract. In order to develop effective measures to ensure the operational condition of the development workings behind the face in the conditions of soft footwall rocks, the construction of local reinforced zones under the protection means has been proposed. The presence of such zones allows transferring the current load deep into the massif and creating a stable foundation under the protective structure. The results of researches concerning establishment of rational parameters of local reinforced zones with application of the method of finite elements, the method of experiment planning and the method of statistical processing of these results have been presented. The empirical dependence of the subsidence of the local reinforced footwall under the protection means on their load, deformation characteristics of the local reinforced zone and host rocks, width of protection means, strength of soft underlying rocks and geometric dimensions of the zone has been determined. The relative indicator of efficiency of local strengthening of a footwall which is used for determining of rational parameters of a locally reinforced zone has been offered.

1 Introduction

Recently, there has been a tendency in Ukraine to reduce coal consumption and switch to alternative energy sources. But coal will not lose its relevance because of its strategic importance to the state, as thermal power plants account for 31% of electricity generation. Nuclear generation has the largest share (55.6 %), but it is import-dependent due to the impossibility of having a closed nuclear fuel cycle within the country [1]. Therefore, the replacement of thermal energy with nuclear energy makes our country energy-dependent.

It is impossible to completely copy the models of European economies, as the level of development of industries, raw materials base, and export and import orientation in Ukraine differ significantly. It is unacceptable that a state that has its own coal resources exports it from Russia and Kazakhstan. In Kazakhstan coal still remains and will definitely remain the main source of energy in the near future, despite the fact that the country is a world leader in uranium mining [2], which has been increased several times over the past 15 years due to underground leaching [2, 3]. As a result, a considerable share of the country's export is accounted for uranium, coal and electricity. Therefore, the extraction and development of mineral resources is a strategically important task for Kazakhstan and Ukraine.

In Ukraine most of the resources are extracted with the underground method in conditions of high mining pressure. For ore deposits the main problem is efficient crushing of strong rocks [4] and ensuring the stability of workings and chambers at depths of 1115-1900 m [5-7], whereas in coal mines the situation is more complicated due to soft adjoining rocks, water content, disturbance of coal seams, and so on. The negative impact of these factors affects the general condition of the mine workings at depths of more than 300 m, especially preparatory ones, which are additionally exposed to actual works.

Coal mines have recently been using the development systems that provide the maintenance of workings behind the faces and construction of protection means on the boundary with the mined-out spaces [8-10]. However, in the case of soft footwall rocks, the protection means are mostly ineffective, as they act as dies [11-13], from which the rocks are extruded into the protected workings, and together with the contraction and subsidence of the means there happen significant displacement of the roof rocks areas around the working and the final section of face. In such conditions the question of providing proper rigidity of rocks under the protection means for maintenance of operational state of the protected workings is topical.

An effective measure in the conditions of soft footwall rocks is to construct the local reinforced zones in the rocks of the footwall under the protection means, the presence of which allows transferring the load into the massif and creating a steady foundation under the protective construction. In this direction, it is necessary to conduct comprehensive research to determine the rational parameters of such zones in specific conditions.

2 Methods

The creation of local reinforced zones on the contour of a working is achieved to ensure its rigidity. This is evidenced by the results of research presented in [14-17]. The idea of making a local reinforced zone under the means of protection was first proposed in [18]. It is provided to place such a zone in soft rocks under the protection means to ensure their rigidity by making a holistic or consolidated construction (Fig. 1) using anchors [14, 19-23] or fastening mixtures [14, 20]. This design is able to withstand the loads coming from the protection means.

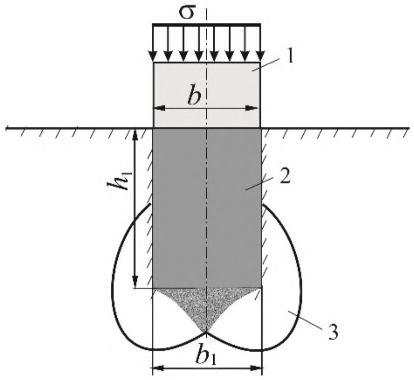

Fig. 1. Schemes of placement of protection means 1 over the local reinforced zones 2 with different shapes and deepening (1 - means of protection, 2 - local reinforced zone, 3 - area of boundary equilibrium, σ and b - respectively, the load on the protection means and its width, h_1 and b_1 - respectively, height and width of the local reinforced zone) [18].

Making under the protection means the local reinforced zone, in which the total deformation modulus is greater than the total deformation modulus of the footwall rocks, allows preparing in advance for the protective structure a rigid base that transfers load onto the massif. It increases the resistance of the footwall rocks, reduces the subsidence of the protective means according to the level of the footwall surface and reduces the displacement of the roof rocks. Since the part of the extrusion force from the foundation is directed deep into the footwall, it reduces the displacement of the footwall rocks in the working.

The efficiency of creation of such zones has been proved by the results of physical (Fig. 2) and numerical simulations (Fig. 3) [18], according to which it has been found that: laying a protective construction below the footwall surface reduces the displacement in the working and save its residual area by more than 82%; the average depth of the local reinforced zone in the range of 0.8≤d/b<2 can be considered effective; to determine rational parameters of the local reinforced zone under the protection means, it is sufficient to limit the parameters that determine the stress state of the underlying rocks, namely: strength and deformation characteristics of this zone under the protection means, its shape, depth and width, as well as the characteristics of the footwall rocks.

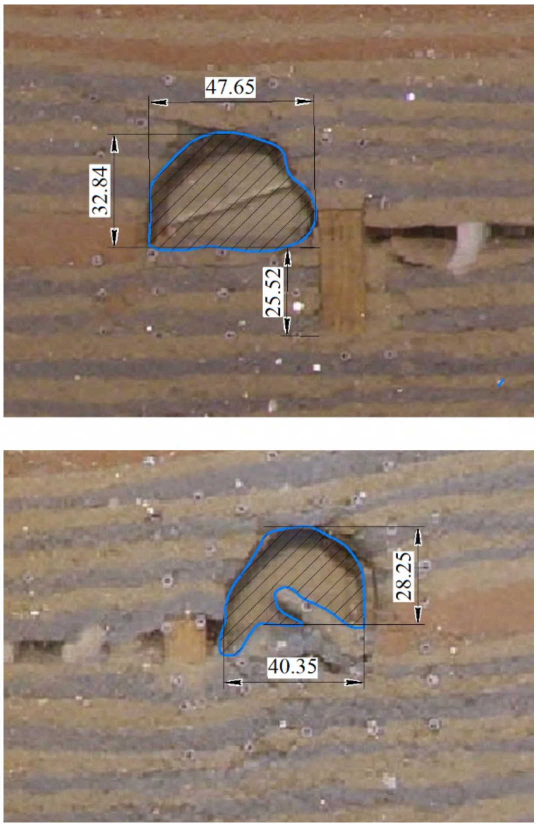

Fig. 2. General view of workings and protective constructions without deepening (a) and with deepening (b) in the model of equivalent materials at the end of measurements.

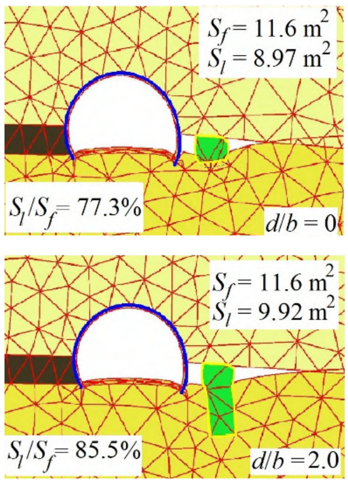

Fig. 3. General view of deformed grids of finite-element models at different relative size of depth of the protection means d/b (d - value of the depth, b - width of the protection means) to determine the relative residual cross section of the working S_k / S_n (S_n, S_k - the cross-sectional areas of the working respectively, before and after the model calculation) [18].

In the simulations it was assumed that the means of protection were under a steady load, and the strength of the local reinforced area was equal to the strength of the material of the protection means. Therefore, the means of protection and the area under it were considered as a holistic construction. Such simplification allows to establish the range of deepening of a construction and to establish the factors which need to be considered at determining parameters of local zones. However, according to the results of the research, it is not possible to determine rational parameters of the zone for certain protection conditions of a working. Therefore, there is a need for additional research that would be devoted to the development of methods for determining the parameters of local reinforced zones under the protection means for specific mining, geological and technical conditions.

3 Results and discussion

To determine rational parameters of local reinforced zones under the protection means, it is advisable to use the results of research as for determining the displacements of adjoining rocks around these means [24] and the effectiveness of laying these zones [18].

Local fixation of the partially destroyed massif and creation the blocks with greater strength than the surrounding rocks allows preserving the integrity of this massif and promotes self-wedging of the destroyed rock blocks in the process of movement [20]. As a criterion for determining the effectiveness of making a local reinforced zone under the protection means, the value of the change in subsidence of the protective construction relative to the surface of the underlying rocks has been proposed. This criterion can be shown by the coefficient k_o. Then

$$k_o = \frac{U_b}{U_b^*}, \tag{1}$$

where U_b, U_b^* - the amount of subsidence of the footwall surface under the protection means, respectively, without any measures and with the construction of a local zone, m.

The value of U_b depends on the magnitude of the load from the protective construction, its width, the strength of the soft layer of the footwall and their compressive properties, so it can be determined from the expression [24]

$$U_b = 0.835 m_v \sigma_o h_n, \tag{2}$$

where σ_o – are the stresses arising at the contact of the protection means and the underlying rocks because of the load, MPa; h_n – is the thickness of the direct footwall layer, m; m_v – is the coefficient of relative compressibility of rocks, MPa^{-1}, which is determined by the expression [25]

$$m_v = \left(1 - \frac{2\mu_n^2}{1-\mu_n}\right) \Big/ E_n, \tag{3}$$

where E_n- is the modulus of the total deformation of the direct footwall layer, MPa; μ_n- is a coefficient of relative transverse deformation of this layer.

This expression has been obtained according to the results of numerical simulation. It has a coefficient of determination R^2=0.9, and correlation - r =0.949, which indicates a strong correlation. In addition, $t > t_{\text{critical value}}$ (75.3>1.96) and $F > F_{\text{critical value}}$ (1883.9>2.62), so the relationship can be considered reliable; the correlation and determination coefficients are statistically significant, and the regression equation is statistically reliable.

According to the results of simulations [18], we can assume that the value of U_b^* depends on the shape of the local zone, its depth and width, as well as the strength and deformation characteristics of this zone and the underlying rocks. Peculiarities of the affect of bearing pressure on the underlying rocks depend on many factors, which include the structure and physical and mechanical properties of interlayer rocks, the angle of a seam inclination, the peculiarities of the development system, the roof control method, and the speed of a face displacement [26]. Let's limit to the parameters that must be changed in the model to establish the functional dependence: the magnitude of the load, the rigidity of the protective construction, its weight, width and height, as well as an indicator that characterizes the compressibility of the footwall rocks.

In general, the dependence of the amount of subsidence of the footwall surface under the protection means, in the presence of a local reinforced zone, from the influencing factors, may be determined by the expression

$$U_b = f(\sigma_o; b; h_1; b_1; \mu_1; E_n; E_1; \mu_n; h_n), \tag{4}$$

where b- is the width of the protection means, m; b_1, h_1– are, respectively, the width and the depth of the local reinforced zone, m; μ_1– is the coefficient of transverse deformations of the local reinforced zone, units; E_1- is the modulus of total deformation of the reinforced massif in the local zone, MPa.

In dimensionless form, the dependence (4) has the expression

$$\frac{U_b^*}{h_n} = f\left(\sigma_o m_v; \frac{b_1}{b}; \frac{b_1}{h_1}; \mu_1; \frac{E_1}{E_n}\right), \tag{5}$$

and includes nine factors. To quantify it, we use the plan of V. M. Mordashev [27] experiment with eight options for each factor, which has the form shown in table 1.

To establish the correlation dependence based on the expression (5), the numerical modeling by the finite element method has been performed [28]. The problem has been solved in a flat design, as the protective construction and the massif under it are elongated in plan and the stresses are distributed in a single plane. There have been constructed the geometric models of a unit thickness, which consist of the layers of direct and main

https://doi.org/10.1051/e3sconf/202128008018

footwall rocks with a local reinforced zone, on which evenly distributed load has been applied locally, simulating the affect of the protective means on the underlying layers (Fig. 4).

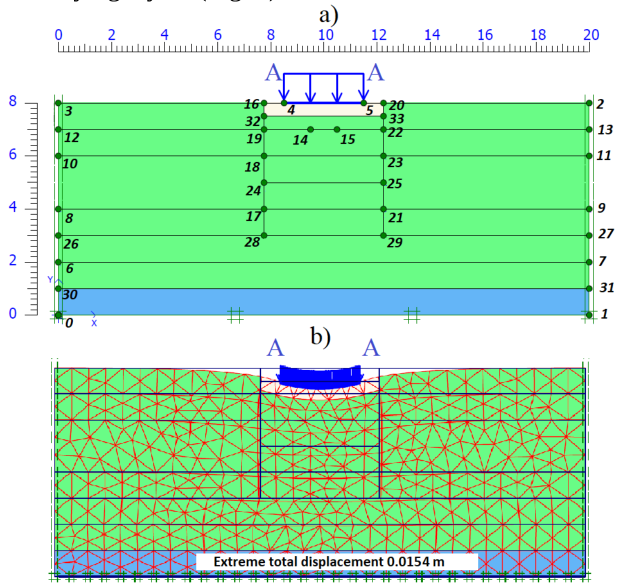

Fig. 4. Numerical model in the data entry window (a) and a finite element grid (b).

To realize the nonlinear nature of deformation of the massif, the elastic-plastic Mohr-Coulomb model has been used. According to the initial data (Table 1), 64 models have been built, during the testing of which the maximum pressing values of the footwall rocks U_b^* under the loading have been obtained. The general view of one of the models by the stages of its development is shown in Figure 5.

Processing of simulation results allowed to establish coefficients of empirical dependence of displacement U_b^* on the main affecting factors, which has the form

$$U_b^* = 0.835\sigma_o m_v h_n \left(\frac{b^2}{h_1 b_1}\right)^{0.163} \left(\frac{E_n}{E_1}\right)^{0.372} \qquad (6)$$

(R^2=0.896; t>$t_{\text{critical value}}$ (23.1>2.0); F>$F_{\text{critical value}}$ (51.7>2.06)), by which it is possible to determine the amount of subsidence of the protection means, under which the local reinforced zone is located.

Thus, from expressions (1), (2) and (6) it is possible to determine a relative indicator of efficiency of local strengthening of the footwall rocks by the formula

$$k_o = \left(\frac{h_1 b_1}{b^2}\right)^{0.163} \left(\frac{E_1}{E_n}\right)^{0.372}, \text{ (when } b_1 \geq b \text{ and } E_1 > E_n\text{)}, \quad (7)$$

which shows how much the subsidence of the protection means reduces relative to the surface of the underlying rocks when they are strengthened. It should be noted that in some cases, this figure may be less than 1. That is, with the wrong parameters of the local reinforced zone, the effect of its presence may be negative.

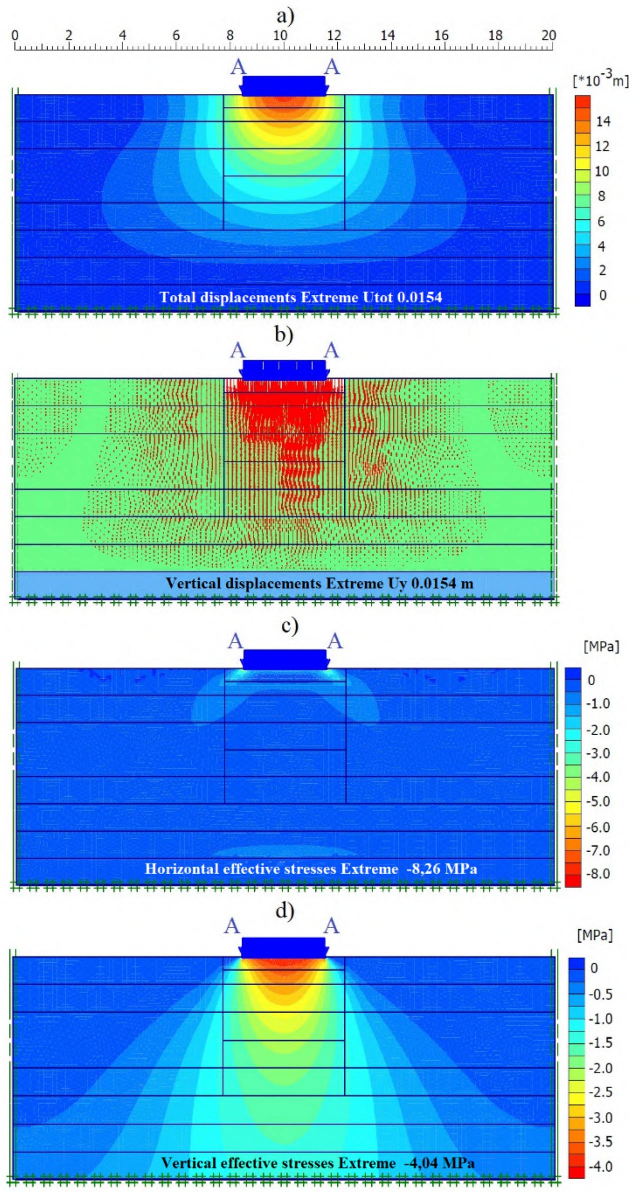

Fig. 5. General view of the numerical model for the study of deformation processes in the underlying rocks with a local reinforced zone (a– finite element grid, b, c, d– results of calculation, respectively, of vertical and horizontal stresses in the underlying rocks).

From expression (7) it follows that the parameters of the local reinforced zone under the protection means to ensure its stability are determined according to the assumption

$$\left(\frac{h_1 b_1}{b^2}\right)^{0.163} \left(\frac{E_1}{E_n}\right)^{0.372} > 1, \qquad (8)$$

according to which it is possible to take the appropriate size of this zone in relation to the width of the protection means and determine the required modulus of the total deformation of the zone in relation to the modulus of deformation of the soft layer of surrounding rocks. The left part of the assumption shows how much the subsidence of the protection means has been decreased with local strengthening of the footwall under it. In the assumption, the width of the local reinforced zone must be equal to or greater than the width of the protection means, and the deformation modulus of the local reinforced zone must exceed the deformation modulus of the soft layer of the footwall rock. Fulfillment of the condition shows the effective ratio of parameters of the local reinforced zone, the means of protection and a weak layer of footwall rocks, which increases the resistance of footwall rocks, reduces subsidence of the protection means relative to the level of the footwall surface, and reduces displacement of the roof and the protected footwall behind the face.

4 Conclusions

As a result of modeling the following conclusions have been made:
- the empirical dependence of the subsidence of the footwall surface under the protection means, below which the local reinforced zone is located, on the main influencing factors such as: load from the means of protection, deformation characteristics of this zone and host rocks, width of the protection means, strength of soft underlying rocks, and geometric dimensions of the local reinforced zone, has been established;
- the relative indicator of efficiency of local strengthening of footwall rocks which is used for determination of rational parameters of the given zone and considers its geometrical sizes, width of protection means, deformation and strength characteristics of a zone and host rocks, has been identified.

This work has been carried out within the framework of the project "Improvement of ways to increase the stability of mine workings in deep mines" (State registration No. 0117U004316).

Abstract. For the time being, moisture effect to the useful quality of coals has been researched comprehensively in detail. Herewith, there are a lot of unsolved problems related to the safety working out of coal layers. Presence of different forms of moisture in fossil coals essentially influences the coal layers hazardous characteristics manifestation during the mining activities. The Article deals with the results of analyses of more than thousand samples of the Donets Basin coals from different deposits, to research the relationship of total moisture and organic matter components in the coal carbonizations during the metamorphic processes. The researches have allowed separation of 3 stages for the fossil coal conversions. It is noted that at the initial stage, the carbon content is about 80%, moisture proportion in carbonization is rather high—0.36; but it decreases abruptly down to 0.12, in case of the carbon content increasing up to 86.5%. And the proportion of components (hydrogen, oxygen, nitrogen, and sulphur) total increases essentially up to 0.88. At the next stage, at 86.5÷91.5%, the components proportion in carbonization changes insignificantly. At the final stage of coal metamorphic conversions, 4-time growth of moisture proportion takes place in carbonization. It is found that moisture proportion in any form to be found in the coals shall be considered as a rank index, which is necessary to determine the coal layers hazardous characteristics.

1 Introduction

Moisture is one of the most important quality indicators of coals. The significant content of moisture has an adverse effect to heating-performance and processing characteristics of coal; it reduces its calorific value and thermal resistance; its grinding, screening, and dressing becomes more difficult; it increases its carbonizing time and other coal processes, and makes its transportation (as ballast) more expensive [1].

To determine the above properties, the total coal moisture content (W) dried out to the constant weight at 105÷110°C shall be found. At the above temperatures, no pyrogenetic and hydrate moisture is removed and takes part in the total moisture content.

For the time being, the moisture influence to the coal useful properties has been researched comprehensively in detail. Herewith, there are a lot of unsolved problems related to the safety working out of coal layers.

Presence of different forms of moisture in fossil coals essentially influences the coal layers hazardous characteristics manifestation during the mining activities.

The significant role of moisture has been found in the gasdynamic events [2] and endogenous fires [3] occurrence, presence of dust-forming capability [4] and explosive properties of the coal dust [5]. These and several other negative manifestations of the coal layers hazardous characteristics are connected with changing the composition and properties of coals during their metamorphic conversions.

Generically, the metamorphism implies the various geological processes, which influence changes in the structure, mineral and chemical composition of coals [1]. Different forms of moisture content in the coals are connected with their metamorphic conversions as well. Determination of moisture content of each form and assessment of their influence to the coal layers tendency to manifest their hazardous properties is related to the mining problems, which are not solved yet [3]. Decreasing of accident risk and rate of injuries in the coal mines strongly depends on their solving and regulatory environment improvement. At its core, the moisture content relates to the metamorphic coal conversion indicators. Its content and forms of presence largely determine the elemental composition of coals and their properties [2-5]

The role of moisture in changing the composition and properties of coals during their metamorphic conversions has no proper reflection in the current Ukrainian regulations [6-9].

It's known that bed moisture in coals decreases as far as the metamorphism intensity increases; however, in

* Corresponding author: tarasov@snu.edu.ua

 https://doi.org/10.1051/e3sconf/202128008019

passing to the anthracites, it increases again [4, 10]. These works used different interpretation of the coal rank definition. In the work [10], one of the main definitions of metamorphism has been kept: increasing the carbon content in the organic matter almost up to 100%, and reducing the total content of other main components down to zero. Keeping these provisions, 10 stages of metamorphism has been established based on the coke yield dry mineral matter free. Based on the analysis of multiple samples, average composition of the Donets Basin coals has been determined in the different coal ranks. The following has been taken under consideration: the content variation of carbon (C_0), hydrogen (H_0), nitrogen (N_0), sulphur (S_0), and oxygen (O_0).

In the work [4], the metamorphism intensity has been assessed by the coal ranks. The ranks as per industrial classifications define their useful quality, and do not reflect any alterations in the coal compositions and properties immediately. The useful quality of coals shall be established per totality of several classification indicators: the content of volatile agents (V^{daf}), coal plastometric index (y), semi coking resin yield ($T_{SK}{}^{daf}$), and free upheaving indicator (SI) [11]. Finally, they indirectly define the coke capacity that is one of the main tasks of industrial classifications. Coal humidity (W) has been considered as an additional criterion of the dust-forming capability [4], which has no direct relation to the metamorphic conversions. The content of volatile agents and coal rank are only indirect characteristics for variation of coal compositions and properties. In the case under consideration, they are assumed to be the key indicators of metamorphism intensity. By nature, V^{daf} and coal ranks are derivatives of component compositions of the initial substance organic and mineral parts during the geological processes. The moisture is an integral component of the fossil coals; its content suffers significant variations in parallel with the other constituents [10, 12]. For this reason, the moisture content in any form may serve as a criterion for the real hazard of coal layers during mining activities. This circumstance has been fully ignored in the regulations [6-9], when estimating the coal ranks.

In all the cases, the bed moisture (W) is considered as an independent indicator, which is not included in the organic matter composition, and independent of the other components content [1, 10, 13, 14]. The yield of pyrogenetic and hydrate moisture shall be included in the composition of volatile substances [10]. These forms of moisture content are not considered in the volatile substances yield, when determining V^{daf} indicator [1, 5, 13-15]. In both cases, the different forms of moisture content have immediate relation to the coal metamorphic conversions; and their indicators may determine the coal layers hazardous characteristics by many aspects.

One of causes of the normative documentation defects in a part of ensuring the safety conditions for mining operations is the proven insufficient previous study of the fossil coal moisture influencing their metamorphic conversion intensity.

Due to this, researches connected with the moisture study as an indicator of the coal metamorphic conversions are important today. The regulatory environment improvement largely depends on their results; it will help to reduce accident risks and rate of injuries in the coal mines.

2 Research procedure

Carbonization is one of the component parts of fossil coal metamorphic conversion processes. By definition [16, 17], it consists in the carbon (C_0) content increasing and hydrogen (H_0) and oxygen (O_0) reducing in the organic matter. In addition to C_0, H_0, and O_0, variation of the nitrogen (N_0) and sulphur (S_0) [10] content takes place in the organic matter during the metamorphic processes.

As rule, the total content of C_0, H_0, O_0, N_0, and S_0 is at least 99% of the whole organic matter. For this reason, the carbonization indicator values (C_n^{Σ}) in all the coal ranks shall be determined by the ratio:

$$C_n^{\Sigma} = \frac{C_0}{H_0 + O_0 + N_0 + S_0} \tag{1}$$

Consideration of such an aggregate of components helps to determine C_n^{Σ} more correctly.

The work procedure is actually based on the functional dependence of the totality of considered organic matter components on the carbon content [18, 19]. This provision is confirmed by the experimental data concerning variation of the components (H_0, O_0, N_0, S_0) totality depending on the carbon content in organic matter (Fig. 1, Curve 2). The information concerning variation of the components H_0, O_0, $N_{0,}$ and S_0 totality depending on C_0 content as per [10] is shown in Table 1.

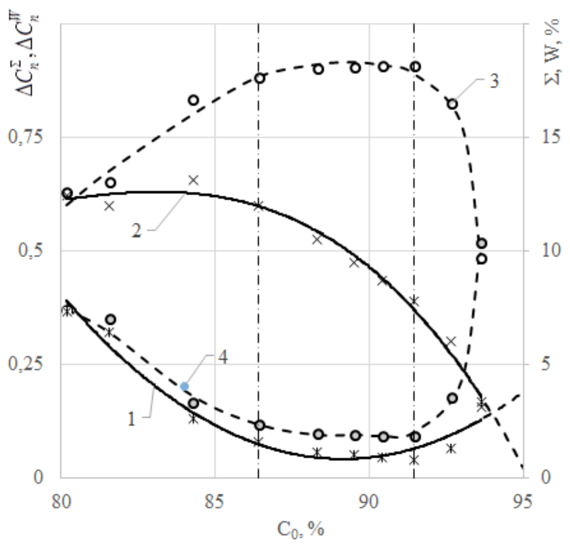

Fig. 1. Dependence of moisture variation (W) and total (Σ) of other components in the coal organic matter as per [10] and determination results of their part in coal carbonization Σ(H_0, O_0, N_0, S'_0) on the carbon content (C_0):
1, 2 – history curves of moisture and organic matter elements total, respectively; 3, 4 – history curves of part of organic matter elements total and moisture, respectively.
I, II, III – carbon content variation ranges, respectively 80÷86.5; 86.5÷91.5%; and more than 91.5%.

Table 1. Information concerning content in the moisture samples (W), and organic matter components as per [10], and results of determination of their part in the coal carbonization.

Indicators	**Content in moisture samples, and organic matter components, and carbonization parameters at content of C_0, %**									
	80.19	81.57	84.29	86.43	88.33	89.53	90.43	91.46	92.67	93.65

At the same place, the data on bed moisture in the coal samples, which correspond to the total moisture (W) at the considered coal rank (C_0 content), are shown.

Dependence diagram of W on C_0 changes ambiguously (Fig. 1, Curve 1). During increasing the carbon content up to 86.5%, the moisture content in coal samples is reduced rather intensively by non-linear dependence from 7.34 down to 1.59%. In the carbon content increasing interval of 80÷86.5%, reducing of W content takes place less intensively in linear fashion from 1.59 down to 0.78%. Then, in the carbon variation range of 86.5÷91.5%, the moisture content growth starts from 0.78 up to 3.32%.

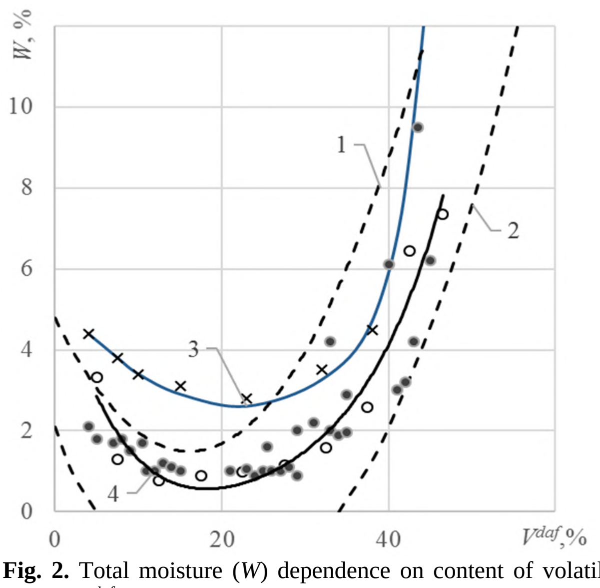

Fig. 2. Total moisture (W) dependence on content of volatile agents (V^{daf}) as per data processing [19].

1, 2 are upper and lower limits of moisture content variation in coals [5], respectively; 3, 4 are history curves of averaged moisture values as per [4] and [10], respectively

Such a variation of bed moisture is confirmed by the statistical data [5, 12-14] processing results [19] (Fig. 2). Curve 4 of the averaged data as per [10] is within limits between curves 1, 2 of potential individual variation values W for coals of different coal-bearing basins. It witnesses about the initial data [10] reliability, which have been received from the average results of analyses of more than thousand samples of the Donets Basin coals.

3 Discussion

Organic matter conversions under elevated temperatures and pressure are complex by nature. The vector direction of organic substance composition variation in case of the metamorphism intensification from lignites to bituminous coals, and then to anthracites is characterized by the carbon content increasing approximately from 70 up to 97-98%, and by the respective reducing of other components totality. For a certain coal layer, content of each main component of organic matter—C_o, H_o, N_o, S_o, O_o, and W – shall be determined by their initial ratio and fluids removal conditions during the metamorphic processes. The combined total of decreasing components (H_o, N_o, S_o, O_o, W) content shall be controlled by the carbon C_o content. Dependence of the main components (H_o, N_o, S_o, O_o) total on carbon content is characterized by the functional dependence by nature.

When C_o is increasing, individual reduction of the main components content is not so unambiguous. As rule, their links are subjected to non-linear dependences; and in some cases, there are abnormal deviations of some main components from the averaging curves. It evidences about differences between metamorphic conversion intensities of the certain coal layer and averaged indicators. Consequently, the elemental composition and properties of such coal layers will differ from the averaged indicators. These individual differences depend on the content of each component in organic matter. In the course of metamorphism, the oxygen content is reduced monotonously from 20-30% almost down to zero. During increasing the carbon content approximately from 70 up to 87-88%, the hydrogen content is unchanged and within the range of 4-6%. Its abrupt decreasing down to proportions of percent takes place in case of further growth of the carbon content. Reduction of the nitrogen takes place, when the carbon content is more than 95%. The sulphur percentage is almost unchanged in all the coal ranks. For separate coal layers, the total sulphur content may be less than one percent. There are cases of its maximum content up to 10%. The elemental individual content of each component of organic matter characterizes some region of the coal layer metamorphic conversion. Combinations of C_o, H_o, N_o, S_o, O_o, and W relations form the individual properties of coal layers, which are manifested during the mining operations. Work out experience of the separate coal layers and accumulated modern statistical material allow using the analysis results of coal laboratory samples with definition of C_o, H_o, N_o, S_o, and O_o. In majority of cases, the modern methodology of moisture determination is related with its drying up to the coal sample constant weight. For this reason, it is not always possible to designate W indicator as dry ash-free organic matter in combination with C_o, H_o, N_o, S_o, and O_o. The majority of organic matter components are intercorrelated between themselves. They include moisture content as well. W indicator depends on the carbon content, and its non-linear link with the oxygen content is established as well. It evidences that in the first factor block, which determine the coals ignitability, as minimum, it is necessary to consider the elemental relation between C_o, H_o, N_o, S_o, and O_o. Content of each of these components individually characterizes one of the aspects of coal layers metamorphic conversion processes. Variation of their relation indicates appearance of the different coal properties in comparison with the previous coal rank.

Based on its unilateral quantitative variation tendency, the carbon is a key indicator of the metamorphic processes intensity. The other components (H_o, N_o, S_o, O_o, W) supplement their characteristics. The most intensive variation takes place in the oxygen and moisture elemental content. The hydrogen content is decreasing essentially in the final metamorphic stages. Minimum variations are observed in the nitrogen and sulphur content. Rank order of the components—H_o, N_o, S_o, O_o, W—based on their part in the carbonization (C_o growth) in the different metamorphic stages influences the chemical activity of coals, including their liability to spontaneous ignition. The most ignitable coals are those, which have the leading places of oxygen, moisture, and sulphur in the rank order by the carbonization indicator.

Using the initial data (Table 1) on relation of the carbon C_0 variation and total of other components (H_0, O_0, N_0, S_0) of organic matter, by equation (1), the carbonation indicators C_n^{Σ} numerical values have been determined in the different coal ranks.

The indicators C_n^W (Table 1), which correspond to the carbonization intensity (C_0 increase) at the moisture (W) reduction in samples, have been considered by the equation:

$$C_n^W = \frac{C_0}{W} \tag{2}$$

The indicators C_n (Table 1), which characterize the general carbonization at decreasing the total of all the components (H_0, O_0, N_0, S_0) of organic matter and bed moisture (W), have been determined based on the dependency:

$$C_n = \frac{C_0}{H_0 + O_0 + N_0 + S_0 + W} \tag{3}$$

The carbonization indicators C_n, C_n^{Σ}, and C_n^W are interrelated between themselves by the relation:

$$\frac{1}{C_n} = \frac{1}{C_n^{\Sigma}} + \frac{1}{C_n^W} \tag{4}$$

Values of the indicators $\frac{1}{C_n}, \frac{1}{C_n^{\Sigma}}$, and $\frac{1}{C_n^W}$, which correspond to the define metamorphic conversion stage (C_0 content) are shown in Table 1.

Having taken $\frac{1}{C_n}$ value to be one, for each stage of the coal conversion, parts of ΔC_n^W and ΔC_n^{Σ} in the general carbonization have been found for moisture and total of other components:

$$\Delta C_n^W = \frac{\frac{1}{C_n^W}}{\frac{1}{C_n}} = \frac{C_n}{C_n^W} \tag{5}$$

$$\Delta C_n^{\Sigma} = \frac{\frac{1}{C_n^{\Sigma}}}{\frac{1}{C_n}} = \frac{C_n}{C_n^{\Sigma}} \tag{6}$$

The numerical values of indicators ΔC_n^W and ΔC_n^{Σ} evidence about continuous variation of the relation of parts of organic matter components totality (H_0, O_0, N_0, S_0) and moisture (W) in the different stages of coal conversion (Table 1, Fig. 1). It evidences that in these stages, the coal layers hazardous characteristics will be manifested differently based on the relation between part of moisture and other components.

At the initial stage of the fossil coal conversion ($C_0 \approx 80\%$), the part of moisture in carbonization is high enough ($\Delta C_n^W \approx 0.36$). It decreases abruptly down to 0.12 (Fig. 1 Stage I) at the carbon content increasing approximately up to 86.5%. The part of other components (H_0, O_0, N_0, S_0) increases essentially up to 0.88. At the following stage (II), the parts of components in carbonization change to a small extent, at C_0 content variation in the range of 86.5÷91.5%. At the final stage (III) of coal metamorphic conversions ($C_0 > 91.5\%$), the abrupt growth of moisture part (up to 0.52) in carbonization takes place. The analogous decreasing the organic matter components part is down to 0.48 (Table 1, Fig. 1).

Ambiguous change regularities of components of elemental compound of organic mass and various shares of their participation in carbonization are revealed. This allows to establish distinctive signs of separate stages of metamorphic transformations of coal. To reliably predict the dangerous properties of coal seams during mining operations, it is necessary to establish the peculiarities of the processes at individual stages of metamorphic transformations of coal. Each stage of metamorphic transformations of coal must be characterized by at least the following indicators: the percentage of carbon in the organic mass; moisture content; elemental composition of organic matter (hydrogen, nitrogen, oxygen, sulfur); the share of organic matter and moisture components in the carbonization of coal; the direction of change in the percentage of each component of organic matter and moisture with increasing carbonization; the direction of change of an individual share of participation in carbonization of components of organic weight and moisture. Given the actual differences in the elemental composition of the organic mass and moisture content, the prediction of the hazardous properties of each coal seams must be carried out according to the adjusted initial data. The share of participation in the carbonization of coal can be affected by changes in any component of organic matter and moisture. Oxygen, hydrogen, sulfur and moisture play a special role in the manifestation of the dangerous properties of coal seams. The possibility of clarifying the characteristic stages of metamorphic transformations is represented, for the most part, by the results of technical and elemental analyzes of coal. If necessary, in addition to them, it is possible to use data on the petrographic composition of coal. These features of changes in the composition and structure of coal during metamorphic transformations under the influence of moisture are not considered in regulations when determining the hazardous properties of coal seams. These variation particularities in the coals structure and composition during their metamorphism under influence of moisture are not considered in the regulations upon the coal layers hazardous properties determination.

Conclusions

The conducted researches allow making the conclusions important for the legal environment improvement:

1. The different forms of moisture in fossil coals significantly determine the coal layers hazardous properties: the gasdynamic events, liability to spontaneous ignition and dust-forming capability, coal dust explosibility.
2. Metamorphic conversion intensity during establishing the coal layers hazardous characteristics shall be determined by the useful quality indicators (content of volatile agents, coal plastometric index, semi coking resin yield, free upheaving indicator), which cannot directly characterize changing the elemental composition and properties of fossil coals.
3. Metamorphic conversions intensity is characterized by increasing the carbon content and decreasing the other components in organic and mineral parts composing the fossil coals.
4. Method to found the bed moisture part in coal carbonization has been developed.
5. Study of relationship between the general moisture part in carbonization and that of total of other components of the organic matter evidences not only about the elemental composition conversion, but about the coal inner structure as well.

Content of any form of moisture in the coals shall be considered as the rank index necessary to establish the coal layers hazardous characteristics.

Rock pressure relief is the basic alternative for sustainable underground mining

Abstract. Retreat longwall mining is the most productive system for underground extraction of tabulated deposits. However, the steady growth of the mining depth dramatically increased the ground pressure in chain pillars protecting the longwall entries. Therefore, several coal industries have tried to shift to pillarless mining and practiced maintenance of the head or tail entry behind the longwall in the stress relief zones using the backfill bodies in the thin coal seams. We modernized the pillarless variant of the retreat longwall system introducing the third roadway, which is driven in the consolidated goaf behind the moving longwall in a stress relief zone. We used a computer code FLAC3D to simulate stress redistribution during pillarless extraction of adjacent panels that assisted to determine optimal parameters of mining layout. This modernized technology provides for sustainable mining due to enhancement of transport, ventilation, safety conditions, and a comfortable environment because of the stability of the underground roadways, which serve the high productive longwalls.

1 Introduction

Shallow reserves of energy resources have depleted since the middle of the twentieth century. The depth of mining has increased steadily that was followed by the intensifying of the ground pressure. For example, the average depth of the underground coalmines in Europe exceeded 700 m. Several mines in Ukraine and China extract the coal at the depth of 1000 m and even more, which increased severe ground pressure manifestations such as gas, coal, and rock bursts, and spontaneous coal combustion. Also, the growing ground pressure augmented the problem of the underground roadway maintenance deteriorating its stability radically [1]. The worst of all is that the aforementioned problems have worsened sharply and unexpectedly.

The reason lies in a nonlinear response of underground roadways to the ground pressure raise [2]. Specialists in geomechanics use a simple but reliable empirical indicator that is a ratio k of the vertical stress component of ground pressure σ_v to unconfined compression strength (UCS) σ_c:

$$k = \sigma_v/\sigma_c \qquad (1)$$

If $k>0.33$ then the stability of an underground roadway fails dramatically since the convergence of the roof to floor and between sides of the roadway increases abruptly. Furthermore, the rate of convergence increment develops as the k exceeds 0.33.

The underground roadways present the main part of the underground mine fixed assets. Therefore, their deterioration dramatically inflates the total cost of extracted mineral resources. Meantime, world coal extraction has steadily grown because the demand for minerals and coal particularly raises.

Therefore, the task of maintaining the underground roadways' stability at the great depth has become a challenge.

The purpose of this presentation is to develop a prospective longwall technology using the maintenance of the roadways in the stress relief (SR) zones. In the second paragraph, we outlined the methods for the investigation of ground pressure redistribution during the pillarless panel extraction. Analysis of the traditional chain pillars system and substantiation of a new system using the third extra roadway has been described in the third paragraph. Then we investigated ground pressure redistribution during pillarless panels' expansion that helped to determine optimal parameters of the novel mining layout. Finally, the advantages of the new system have been discussed and the main conclusions outlined.

2 Methods

We used methods of computer simulation to investigate stress distribution and ground deformation around underground workings. The finite element algorithm (FEA) and finite difference methods are the most powerful and popular techniques, which are employed to solve complex problems when the stress-strain state of the rock mass should be investigated regarding nonlinear behaviour of the rocks and especially processes of their damage [3]. FEA successfully has been used during simulation of hydro-fracturing of the rock mass by SC-

* Corresponding author: kusenab@gmail.com

CO_2 mixture [4], fluid dynamic simulation [5], induced microseismicity by hydro-fracking [6], modelling of fracturing processes in discontinuous, porous rock masses [7].

The finite difference methods (FDM) are even more sophisticated for the simulation of geomechanical processes [8]. Alghalandis used FDM to improve discrete fracture network engineering [9], Bouzeran et al. simulated ground support performance in highly fractured and bulked rock masses [10], Bai et al. conducted numerical investigations of gateroad system failure induced by hard roofs in a longwall top coal caving face [11]. That is why we employed FLAC3D commercial code to simulate underground roadways behaviour in deep coalmines [12].

FLAC3D uses the explicit calculation cycling that propagates perturbation from an unbalanced force damping equations of motion that simulates dissipation of kinetic energy, Also, Cundall and Strack proposed an approach [13], when the calculation of motion (Newton second law) was solved ahead of the constitutive equation describing the stress-strain relation, including nonlinear behaviour of the rock. This imitated the real physics because the velocity of a disturbance wave is always limited in solid and liquid. This approach has provided success in preventing numerical instability and reproducing a realistic path of loading during simulation of nonlinear behaviour of the rock mass.

We also used physical modelling of irreversible ground movement to investigate the redistribution of ground pressure during consequent extraction of coal seams with longwall faces. Synthetic material that simulated a rock mass was a mixture of fine sand with plaster and mica.

Actual measurements of ground movement and deformation provided final and the most reliable data for confirming the results of computer simulation and physical modelling.

3 Chain pillar technology and its alternative

The longwall technology is the most popular in underground mining of tabulated deposits because of its exceptional economic efficiency. The majority of the coal reserves are extracted by retreat longwalls because the advanced longwall movement envisages driving the entries behind the moving face. In other words, the advanced longwall face moves blindly, which exposes it to the risk of impact with an unforeseen geologic fault.

A chain pillar system has been successfully used in US and Australia coalmines during the longwalls retreating since the middle of the last century to mine coal at a shallow and average depth (Fig.1). Longwall panel is outlined with at least two head entries 1 and 2 and tail entries 3 and 4. The head and tail entries are periodically connected with crosscuts 5. Longwall face 6 moves in Fig. 1 to the right as indicated by empty arrow and remains behind itself an empty waste area or goaf 7.

To provide safety, longwall 6 is ventilated by fresh air stream indicated by solid arrows. Mixture of air and methane/carbon oxide is removed through tail entry 4 as is indicated by intermitted arrows.

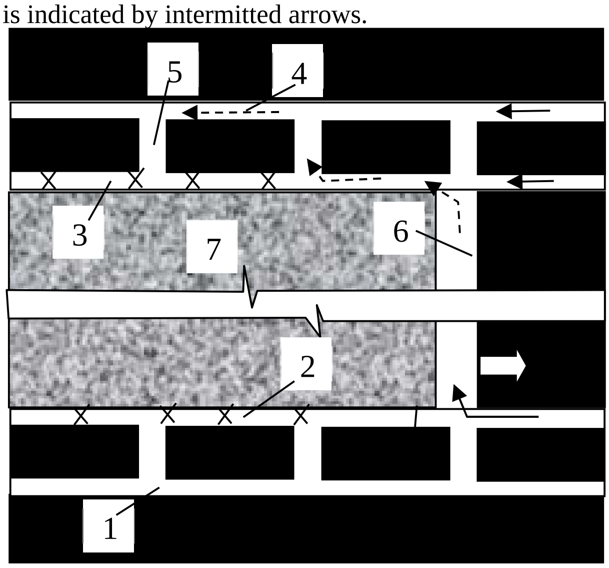

Fig. 1. Layout of the chain pillar system during the first longwall retreat: 1, 2 – head entries; 3, 4 – tail entries; 5 – crosscuts; 6 – longwall face that moves in direction indicated by the empty arrow; 7 – goaf; solid arrows indicate the stream of fresh air whereas intermitted arrows show the movement of the air and methane mixture; crosses specify uncontrolled parts of entries

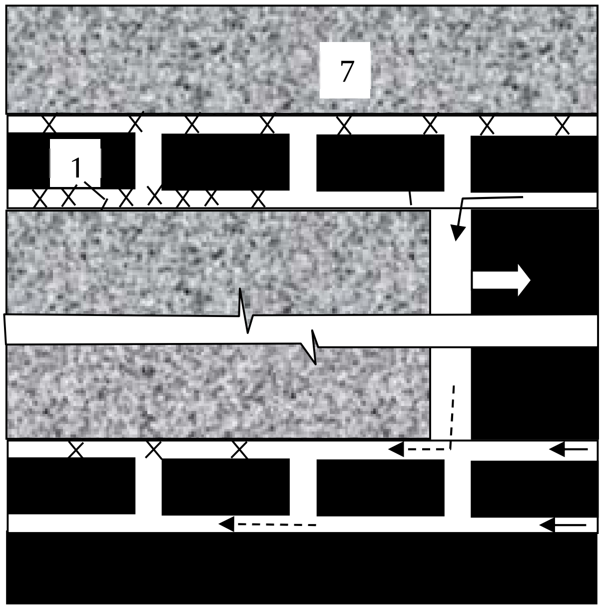

Fig. 2. Layout of the chain pillar system during the next adjacent panel extraction; numerals and arrows indicate the same positions as in Fig. 1

The ground pressure destroys head entry 2 and the crosses indicate an uncontrolled part of tail entry 3 behind the longwall. The next adjacent panels are extracted reusing head entry 1 as a tail entry (Fig. 2).

The content of the dangerous coal methane or carbon dioxide increases coherently with the growth of the depth that raises the probability of rock and coal bursts. That is why practitioners prefer to use Y-shape ventilation system, which provides moving both fresh air and a mixture of air and methane in the same direction as is indicated in Fig. 1. Opposite to the face advance, codirected movement of the air and contaminated gases pushes the dangerous gases out of longwall face and drifts them to the depth of the goaf promoting safety. This system envisages maintenance of the head entry behind the moving longwall where intensive ground pressure causes extensive damage to the roadway. The chain pillars are remained behind the longwall to eliminate this negative effect of the ground pressure.

The idea of the chain pillar technology was based on reusing the head entry 1, which is extreme relatively the goaf boundary. This entry is used again during mining the next adjacent panel (Fig. 2). The head entry, which was close to the goaf boundary, is destroyed after the extraction of coal in the previous panel. However, the extreme head entry ought to be saved and reused as a tail entry for the next panel.

All entries in the chain pillar system are maintained in abutment zones, which concentrate ground pressure and deteriorate the entries. Therefore the more depth of mining the more intensive the abutment pressure is. This situation demands to increase the width of the chain pillars but enlarging the pillars' dimension does not help essentially because of the high overall level of the ground pressure. For example, the index *k* of the roadway stability increases up to 0.5>0.33 at the depth of 800 m and UCS of 40 MPa.

That is why a relevant area of the chain-pillar system implementation is limited by 450-500 m. In other words, the steady growth of the mining depth dramatically increased the ground pressure and excessively wide chain pillars become unacceptable. Therefore, several coal industries, for example, Chinese and Ukrainian have tried to shift to pillarless mining [15] and practiced maintenance of the head or tail entry behind the longwall [14].

US regulations forbid driving of a single underground roadway due to certain ventilation risks. However, European and Asian countries allow such driving. This circumstance made it possible to get rid of the chain pillars and apply Y-shaped ventilation system. In order to do this, the head goaf-side entry 2 was retained behind the longwall face using a roadside backfill body [16], [17], or an artificial wall [14] (Fig. 3).

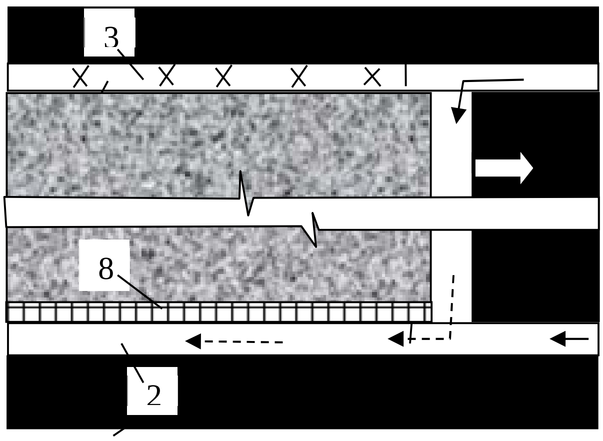

Fig. 3. Mining design with the artificial wall 8

Designers conceive to maintain the head entry with the cement backfill body, which should save stability and integrity during its reusing in the course of the next panel extraction as is shown in Fig. 4.

Reusing the head entry during pillarless mining is a very attractive idea because it saves labour, materials, and energy. However, as far as we know, a successful experience of reusing the head entry, which was driven before the longwall extraction and retained behind this longwall has not been published. Furthermore, several authors emphasize that even retaining and maintenance of an entry behind the advancing (not retreating) longwall is not an easy task at a great depth [16], [19], [18]. That is why the artificial wall technology has been enhanced by a roof cutting to relieve stress at the goaf side [20], [21].

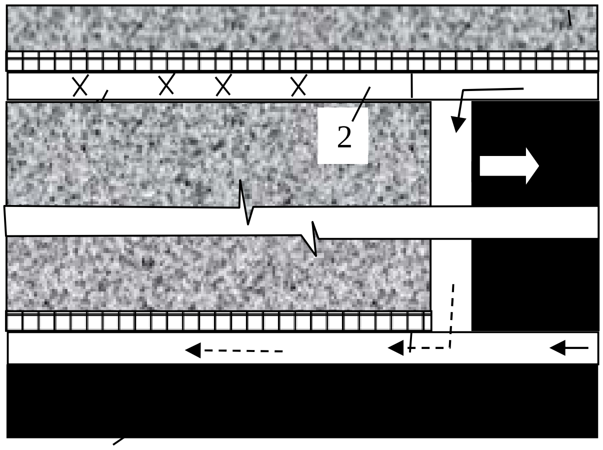

Fig. 4. Mining of an adjacent panel reusing head entry 2

Feng and Wang [22] described an original innovative technology of SR. The entry was planned to be driven under the goaf edge employing split-level longwall panel layout. However, such a system is relevant for the thick coal seams having the height, which exceeds more than two heights of the gateways.

4 Investigation of ground pressure evolution during pillarless mining

SR formation around the roadways has a long history and tradition. We consider the most popular technologies, which have proven their efficiency in the mining practice. Analysing any SR technology we should keep in mind that the relief from the high level of stress is inextricably linked up with a yielding. To get certain unloading from the ground pressure we should be ready to provide some deformation, which will reduce the area of a roadway section.

Zhan et al. [14] investigated a retained goaf-side tail entry, which has been maintained by means of building the artificial wall along the goaf side when the longwall face advanced. The roof of the roadway was reinforced by rock bolts and long 5-metre cables having a total bearing capacity of more than 400 kN/m^2. Despite this, the roof of the entry subsided to 500 mm whereas the floor heaved up to 1700 mm, which deteriorated the roadway section unacceptably when the longwall face had moved a considerable distance. Therefore, the entry has been repaired to a large extent.

The integrity of the artificial wall was checked, and the cracks and fissures on the wall surface were filled to

 https://doi.org/10.1051/e3sconf/202128008020

prevent water and gas in the goaf area from flowing into the roadway space during maintenance.

The floor was dinted to recover the working space for the following operations. This made it possible to remove the squeezed part of the coal side of the roadway. As a result, initially installed rock bolts and cable bolts were exposed due to the widening of the entry. The extra ends of the bolts and cable were cut off, and the retained portion inside the surrounding rock was prestressed again.

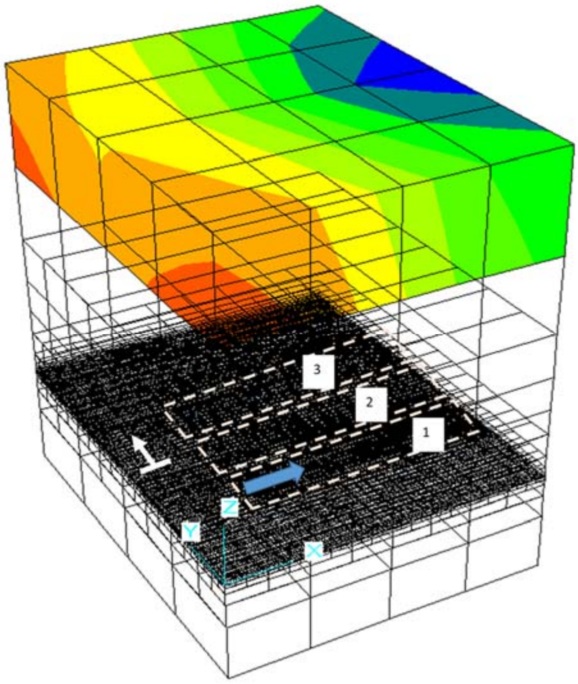

Fig. 5. Layout of the model; numbers indicate the sequence of panels extraction.

According to [14] the roadway section has been recovered and satisfied the requirements of the adjacent panel excavation. However, there was no information concerning the experience of this important part of mining. Pillarless extraction of a panel adjacent to a previously formed goaf causes an extensive ground pressure intensification there, which inevitably will worsen ground control and maintenance of the roadway. To investigate this process, we have carried out a computer simulation of the ground pressure redistribution during adjacent panels' extraction.

Fig. 5 demonstrates the layout of three panels extraction without abandoning inter-panel pillars. The vertical dimension of the model was 1500 m and a flat 1.5-meter coal seam was at the depth of 1100 m. The dimension of the model along the strike (axis X) was 1024 m and alongside with the dip (axis Y) 1240 m. The direction of the panel retreat is indicated by the fat arrow. Every panel had a width of 256 m and located relatively model boundaries at 256 m. The step of the longwall retreat was 10 m that was moving at the rate of 250 m per month.

We used Mohr-Colomb law as the constitutive model of the rock mass. We also accounted for the process of softening due to the rock damaging involving elements of Hoek-Broun empirical rules. The cohesion of the rock dropped down to 1.0-0.5 MPa when dilation strain reached up to 0.004.

The thickness and mechanical properties of the rocks are presented in Table 1, and Fig. 6 shows the vertical movement of the rock mass after extraction of the first panel. Geologic and geomechanical conditions describe those, which were at a typical deep coal mine 'Pocrovs'ke' in Ukraine.

Table 1. Properties of the rock layers in the model

Rock	**Thickness, m**	**Bulk modulus, GPa**	**Shear modulus, GPa**	**Cohesion, MPa**	**Angle of friction, degree**	**Tension limit, MPa**	**Dilation, degree**
Rock	Cover & Base	14.0	8.4	9.0	35	7.0	10
Sandstone, roof	20.0	24.0	14.4	12.0	28	9.0	9
Shale, immediate roof	10.0	14.0	8.4	7.0	28	5.0	10
Coal	1.5	14.0	8.4	7.0	28	4.0	11
Shale, immediate floor	10.0	14.0	8.4	9.0	28	5.0	10
Shale, floor	20.0	14.0	8.4	12.0	35	9.0	10

Elastic recovery of the floor was 40 cm, which is close to 34 cm registered in situ using levelling at the depth of 915 m. This simulation has been conducted in 'set large' displacement mode, which envisages recalculation of the node coordinates according to current increment of the displacements.

Fig. 7 demonstrates the distribution of the vertical stress component around the goaf of the first panel. Average vertical stress in the goaf does not exceed 8 MPa that 3.36 times less than geostatic level, which was 27 MPa.

Furthermore, the stress diminished down to 3 MPa in the immediate vicinity of the goaf border 1 that is nine times less than the geostatic level.

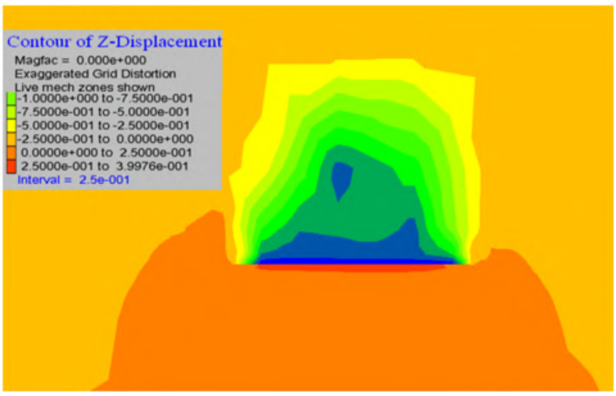

Fig. 6. Contour of the vertical displacement after the first panel extraction.

 https://doi.org/10.1051/e3sconf/202128008020

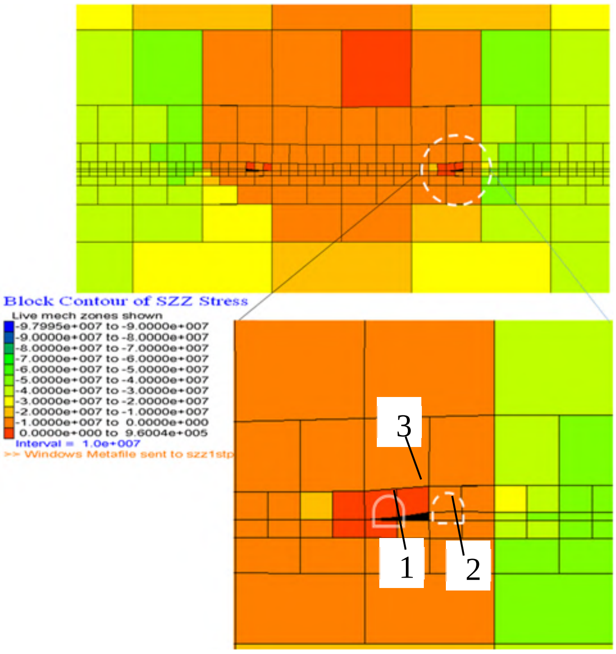

Fig. 7. Distribution of the vertical component of the ground pressure after the first-panel mining.

Position 2 in Fig. 7 indicates the edge of the coal seam that is adjacent to the goaf boundary 3. This area was essentially relieved of the ground pressure reducing it down to 10 MPa. Therefore, miners drive the roadways in the aforementioned area that got traditional characteristics as ‘skin-to-skin’ driving.

Roadway 1 is in a highly favourable position because of an extremely low surrounding stress. Such roadways have been driven in the goaves of Ukrainian coalmines since 1960th. SR zones attracted practitioners to place the roadways in the goaves (Fig. 8). The stability of these gateways was excellent for a long period while the goaf boundary was fixed. However, the roadway state has worsened as an adjacent to the boundary panel was mined. Therefore, we should examine the case when the adjacent panel will be extracted.

Fig. 8. An example of good stability of a roadway driven in compacted and consolidated goaf.

Fig. 9 demonstrates that pillarless extraction of the adjacent panel reduced SR in the goaf of the previous panel. For example, ground pressure in the goaf after extraction of panel 2 was approximately 12 MPa. However, pillarless extraction of the third panel essentially increased the stress in the goaf of the second panel. The vertical stress in goaf 2 increased up to 22 MPa that raised k-index up to 0.55>0.33 (Fig. 9), which has worsened the ground pressure background regarding the roadway stability.

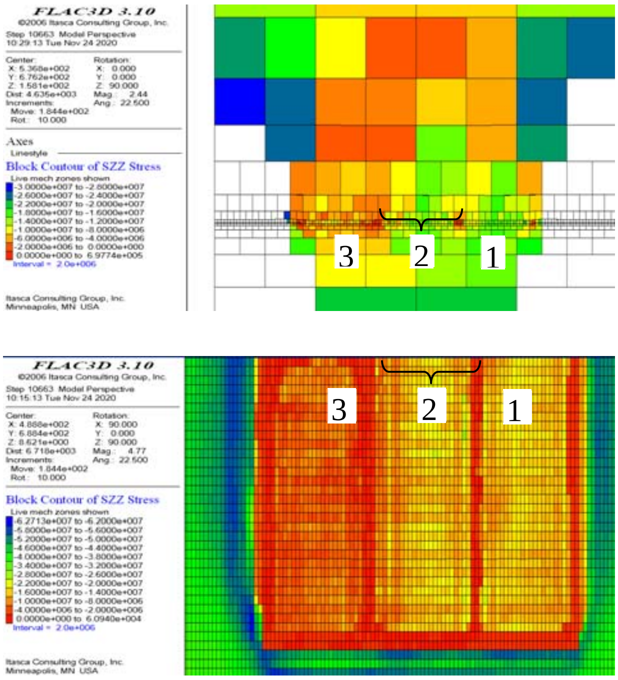

Fig. 9. Stress distribution after extraction of all three panels: vertical section (top); plan view (bottom).

Fig. 10 demonstrates as the k-index evolved during the expansion of mining. Stages from 0 to 2 correspond to the extraction of the current panel whereas stages from 2 to 5 describe the situation when the next (adjacent) panel was extracted.

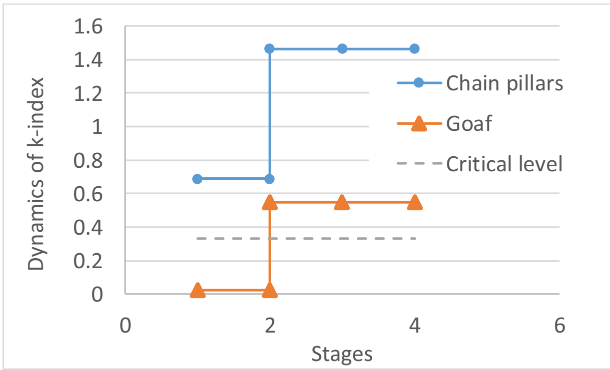

Fig. 10. Evolution of k-index during the extraction of the panels.

The driving and maintenance of the roadway in a goaf is much more favourable than the maintenance of the entries by the chain coal pillars because the ground pressure is less by 30 times behind the current panel and by 2.66 times less after the adjacent panel mining. However, despite this advantage, the roadway in the goaf will suffer because the k-index exceeded the critical level of 0.33.

 https://doi.org/10.1051/e3sconf/202128008020

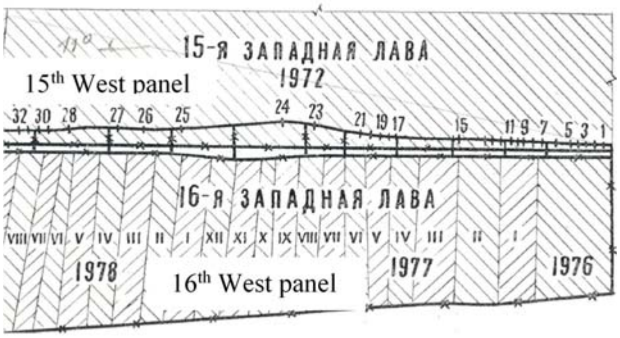

Fig. 11. Mining layout with the third entry drove in a goaf of l_4 coal seam.

The results of the computer simulation have been proven by an experiment in situ (Fig. 11). West panel #16 extracted the flat 1.6-meter coal seam l_4 at the depth of 720 m (the coal mine named after Abakumov, Donetsk, Ukraine) [23]. Weak mudstone having UCS of 20-30 MPa and thickness of 10 m represented the immediate roof whereas medium-strength sandstone deposited in the main roof. Shale with UCS of 30-40 MPa bedded in the immediate floor.

The third entry was driven in 1975 through the goaf of the 15th West panel, which was extracted in 1972. The convergence of the roof and floor in the experimental entry has been periodically measured at the stations indicated by numbers from 1 to 32. Panel #16 was extracted by a longwall with the rate of 30-40 m/month. Roman numbers on the layout in Fig. 11 indicate the month advances.

We selected the monitoring stations from 17th to 20th for demonstration of the third entry reaction to the West longwall #16 retreating. These stations were sufficiently far from the start-up room and reflect a typical periodic roof caving during longwalling.

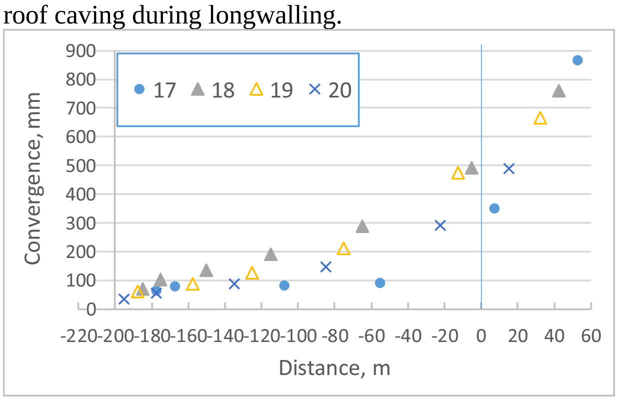

Fig. 12. Results of the convergence monitoring in the third entry.

The negative distance in Fig. 12 points to the position of the monitoring stations before the approaching longwall (outby) whereas positive values of the distance indicate that the longwall passed by the station and moves away from it. The third entry has not been maintained behind the longwall (inby) but there was a possibility to continue the monitoring inby it some period. Fig. 12 shows there was not a subsiding tendency. Furthermore, the convergence had approached up to 0.8 m and steadily continued to grow.

Therefore, additional means are necessary to protect the roadway in the goaf from the negative influence of the adjacent panel mining. The most technological means is the backfill body [24], [25] (Fig. 13).

Roadway 9 is driven behind the longwall. The face of roadway 9 lags to prevent the negative impact of the ground subsidence behind the moving longwall. Distance D should protect the roadway stability and secure that it will be driven in a completely consolidated goaf.

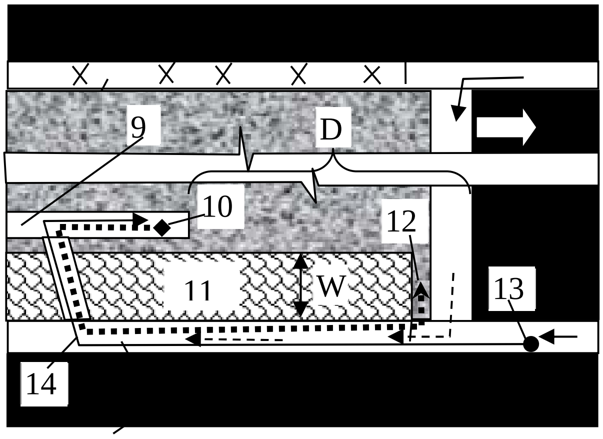

Fig. 13. Mining layout during driving of the roadway 9 in the goaf of the first (previous) panel; 10 – conveyor chain for transportation of the waste rock for the filing of the back body 11; 12 – pneumatic discharge of the crashed waste rock; 13, 14 – local fan and flexible tube for the roadway face ventilation; D – lag distance of the roadway 9 from the longwall.

The waste rock from the driving of roadway 9 is removed by conveyor chain 10, ground by crusher, and packed to the backfill body 11 with pneumatic machine 12. The building of body 11 from the waste rock is viable economically and friendly ecologically. Width *W* of the backfill body 11 is proportional to the section area of roadway 9 and diminishes as the coal seam height increases. For example, W≈25 m when the net roadway section is 20 m^2 and the height of the coal seam is 1.5 m.

Fan 13 ventilates roadway 9 with fresh air, which is collected in front of the longwall face.

Lag *D* of the roadway face depends on the rate of the longwall retreating. For the depth of 1100 m and the rate 300 m/month *D*=245 m (Fig. 14). Such a distance guarantees a perfect stability of the roadway 9 because it will be driven in the consolidated goaf out of active subsidence of the undermined strata.

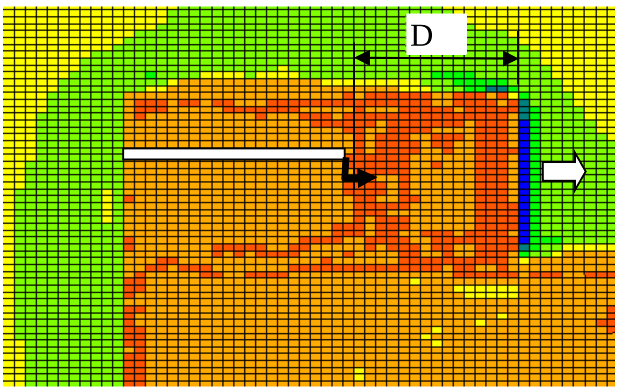

Fig. 14. Distribution of the ground pressure in the goaf behind the moving longwall face.

Fig. 15 shows layout of the mining works during the adjacent panel extraction.

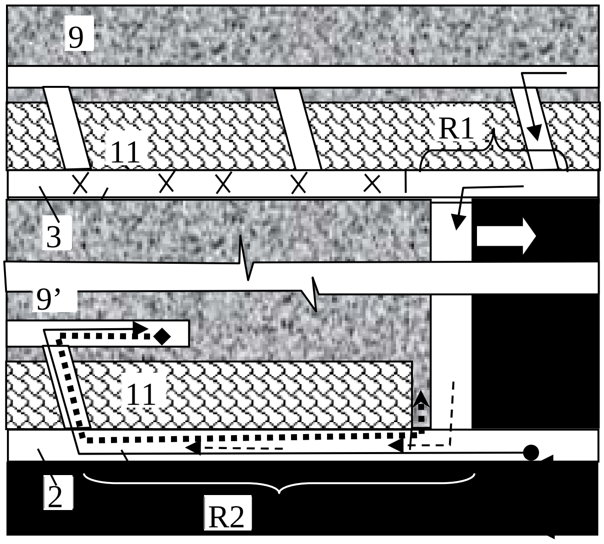

Fig. 15. Mining layout during adjacent panel extraction

This layout has an essential advantage over the chain pillar system. There is no need to maintain entries 2 and 3 through the whole length. It will be sufficient to retain entry 3 between the moving longwall face and the forward crosscut (interval R1), and entry 2 between the longwall and the closest rear crosscut (interval R2). General main service for mining operations will be provided by the roadway 9 and 9': entry 9 will provide the longwall for fresh air and transportation of the coal whereas entry 9' will remove the mixture of air and methane. This is the best variant #1 from the technical point of view and safety consideration.

There is another option #2 when the fresh air stream moving along the longwall reverses its direction, namely goes from the bottom to the top. In this situation, entries 9 and 9' swop their functions but entry 3 must be maintained behind (inby) the longwall, namely from the face to the closest rear crosscut that is not so easy task. Both roadways 9 and 9' will be in a stable state due to protection of the backfill bodies 11 that was demonstrated on the physical model (Fig. 16).

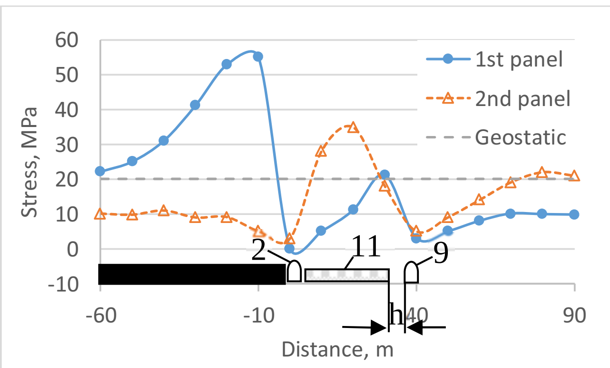

Fig. 16. Stress distribution after 1st and 2nd panel extraction.

The backfill body 11 creates local SR zones at the edges. These zones conserve SR that minimizes the ground pressure activation after the second (adjacent) panel extraction. That is why roadway 9 should be driven in the goaf immediately at the backfill body edge or at the distance h=5-6 m from it.

Mining practice has demonstrated that it is impossible to provide the ideal stability of entries 2 and 3 at the great depth of mining [26]. However, this is realistic to provide minimum means for retaining their intervals R1 and R2 if to use the arch shape of the entries and support them by a combination of yield frames, rock bolts, and cables. Then the dinting of the floor will be sufficient because the self-supporting effect will stabilize the roof [27].

An economic assessment has demonstrated that extra cost of the third roadway driven in the goaf does not exceed 10% of the total profit from the increase of the coal output due to enhancement of transport, ventilation, safety conditions, and comfortable environment because of stability of the underground roadways serving the high productive longwalls.

5 Conclusion

Retreat longwall mining using the chain pillars has become popular in underground mining since the 1960th. However, the steady growth of the mining depth dramatically increased the ground pressure and excessively wide chain pillars become unacceptable. Therefore, several coal industries have tried to shift to pillarless mining and practiced maintaining the head or tail entry behind the longwall in the stress relief zones using the backfill bodies in the thin coal seams.

The mining experience has demonstrated so far that it is not easy to retain entries behind the longwall with the backfill bodies. We modernized the pillarless system introducing the third roadway, which is driven in the consolidated goaf behind the moving longwall and used as a tail entry.

The waste rock from the driving is ground and discharged by pneumatic equipment into the goaf. The backfill body is erected from the waste at hand material immediately behind the longwall face. This backfill support protects the roadway from the ground pressure activation during adjacent panel extraction and reusing of the roadway as a head entry.

The extra cost of the third roadway driven in the goaf does not exceed 10% of the total profit from the increase of the coal output owing to Y-shape ventilation system exploding. New technology provides for sustainable mining due to enhancement of transport, ventilation, safety conditions, and a comfortable environment because of the sufficient stability of the underground roadways, which serve the high productive longwalls.

The authors thank Donetsksteel Company that provided key n ° 024486 for simulation on FLAC3D that is highly appreciated. There is no conflict of interest concerning the results of this paper.

Innovative mining technologies with complex geomechanical characteristics

Dimitar Anastasov[1,*], and *Zdravets* Eftimov[1]

[1]University of Mining and Geology „St. Ivan Rilski“, Department of Mining of Mineral Deposits, Studentski Grad, “prof. Boyan Kamenov” Street, Sofia 1700, Bulgaria

Abstract. The article presents innovative technologies for the extraction of minerals from underground mines with complex geological, mining, and technical and geomechanical characteristics. The need to develop such mining technologies is discussed and the conditions under which they should be applied are presented. Principal variants of extraction technologies such as Raisebor technology, Raisebor technology in combination with the drilling and blasting method and the continuous development system using Alimak or KOV - 25 monorail complex are shown in the article.

The need to develop new technologies

The development of the technologies for mineral processing leads to significant improvement of technical, technological and economic indicators of the overall production. It is possible to process low-grade ores, develop deposits with more complex geomechanical characteristics and achieve a positive economic result. This situation in the mining industry is also helped by the gradual but continuous increase of the prices of the end products produced over the last 15-20 years.

Hence, reassessment of the reserves and adjustments in the commercially useful components in the extracted raw materials are necessary.

Thus, an increase in the amount of reserves is achieved, both in existing mines and in newly created ones. In addition, a certain extension of the operational time of existing mines is also achieved by re-categorizing reserves. Conditions are also being created for the development of new mineral deposits considered to be not very promising (with non-minable contents of useful components).

All this sets up preconditions for creating opportunities for the development of deposits with complex geological, morphological, mining, technical and geomechanical characteristics during the operation of underground mines.

As it is well-known, in the underground mining of complex-structured deposits the classical systems of development are the sublevel stoping method of mining and the square-set stoping-and-filling method of mining with Alimak technology and subsequent mass drawing and caving.

The variants of the sublevel stoping method of mining of deposits with low strength indicators are characterised in two directions: with light portable mechanisation or with mobile mechanisation and front recovery of the ore. In order to do this, a network of opening access roads and inclined development workings for the mining equipment is created. [1] The recovery ratio is 0.9 and the contamination factor is 15 to 20%.

The application of the square-set stoping-and-filling method is universal for this type of deposits and it is characterised by low economic efficiency due to the external production processes such as the support and the filling of the mined-out area. The variants are supports with ¾ wooden frames and wooden lining of the stope or roof bolting with a metal net combined with shotcrete. A high recovery ratio of 0,95 to 0,98 and minimum contamination factor from 3 to 5% are typical for these variants. The Alimak technology is also applicable in complex-structured deposits with shrinkage of the ore. The variant of this technology with open chambers (continuous system) for ore bodies with high dip is not applicable and the caving method of mining of the bedding rocks is used.

In the variants with sublevel caving and the Alimak Technology certain deformations of the surfaces of deposits are admissible which requires additional resources for the reclamation of the damaged lands. The Raisebor technology is used for the extraction of uranium in Canada (Cameco Corporation) [2]. Similar systems have been also described for the development of complex-structured rich iron deposits. [3]

It is important to define correctly the parameters of blasting works, taking into consideration the strain and stress condition of the rock mass when applying these systems for development. [4]

Conditions for the applicability of innovative ore mining technologies in deposits with complex geomechanical characteristics

Innovative technologies for the extraction of minerals are increasingly used in the mining practice for the development of deposits with complex morphology, complex geomechanical characteristics and high value of the mineral resources. The adjusting and reworking of existing development systems and extraction technologies to specific conditions is aimed at finding a solution to a particular problem in a given deposit and not at creating conventional technologies for mass application.

These innovative technologies should be applied in the development of new deposits with complex geological, mining, technical and geomechanical characteristics (ore bodies with complex morphology, ill-defined boundaries, weak ore and host rock strengths, high temperature, etc.), and high value of the extracted raw material.

The objective of developing innovative mining technologies for deposits with complex mining, technical and geomechanical characteristics is to find out a new solution for optimizing yield results. This new engineering solution must be different from the conventional methods of extraction, whereby we will have a positive economic effect (as opposed to classical methods of extraction) from the development of a given deposit.

Raisebor technology

The Raisebor technology consists of extracting vertical layers (rises) from the ore body in a specific order, with the mined out spaces being filled. [5, 6] The primary chambers are filled with a paste-hardening fill to achieve sufficient camera strength to open a secondary chamber next to the filled rock mass without leaving pillars [7]. The secondary chambers can be filled both with a paste-hardening fill and a rock-fill from a sterile mass obtained during the driving of the mining workings.

The purpose of developing a Raisebor technology is to provide a productive mining technology applied in complex morphological and geomechanical conditions. Thus, the loss and impoverishment indicators of the raw materials extracted (without pillar recovery) are reduced. [8].

On the other hand, the technology is designed in such a way so that during the whole stage of operation, the ore extraction is carried out without the presence of people in the mining areas. This ensures safety at work due to the absence of people in the mining areas, as well as the reduction of additional processes for the maintenance of mining areas, ventilation, etc.

Raisebor technology makes it possible to mine ore bodies with complex morphology and ill-defined boundaries. Ore bodies with an average thickness of 0.7 - 2.5 m and an angle of inclination from 90° - to 60° can be mined out. This mining method can be applied to bodies with complex morphology both for the overall development of an underground mine and for its individual sections.

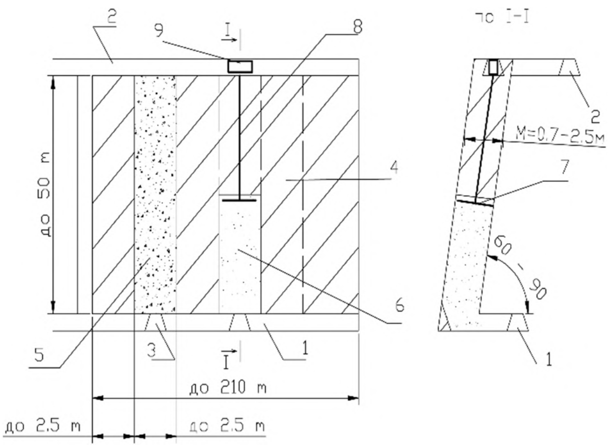

Fig. 1. Raisebor technology for mining of mineral resources
Legend: 1 – haulage level; 2 – air drift; 3 – loading cut-off entries; 4 – ore body; 5 – paste-hardening fill; 6 – fines, extracted ore; 7 – cutting head; 8 – borehole; 9 – Raisebor machine.

The technology offers several options for mining-out:

A - Using stationary mechanization:

- **Standard** – a pilot hole, which expands from the bottom up, is drilled. This method is characterized by a maximum diameter of the side cutting of up to 6 m and a maximum depth of 1000 m;
- **Descending extension** - a pilot hole from top to bottom is drilled, with subsequent top to bottom extension (descending). In this method, the diameter of the working is up to 1.5 m and the depth reached is up to 30 m;
- **Ascending extension** - a pilot hole from bottom to top is drilled, with simultaneous side cutting to the full diameter of the extraction working. Rises of up to 2.5 m in diameter and up to 150 m in depth can be driven by this method.

B - Using mobile mechanization:

- **Ascending driving** - this method is intended for driving a compensation rise in mining systems in sub-level workings, sub-level caving and block caving systems.

The machine operates in workings with 4.5 m x 4.5 m dimensions. This method allows a rise of up to 1.2 m in diameter and up to 200 m in length to be driven.

- **Descending driving**- the method is characterized by a top-down rise with a maximum diameter of 0.75 m and a length of up to 60 m.

The drilling angle varies from 90° to 60° in all directions.

Knowing the capabilities of Raisebor mechanization provides the opportunity to use it as a mining mechanization - to develop an innovative technology for underground extraction of minerals, which strictly meets the specific requirements and characteristics of a given deposit.

It is important to note that the application of the Raisebor technology needs to be well-ensured from a

 https://doi.org/10.1051/e3sconf/202128008021

geomechanical point of view. The geomechanical dimensioning will give the maximum open surfaces that can be naturally sustained. Hence, the specific dimensions of the mining blocks and their parameters should be determined, as well as the specific mechanization and method of driving the extraction workings.

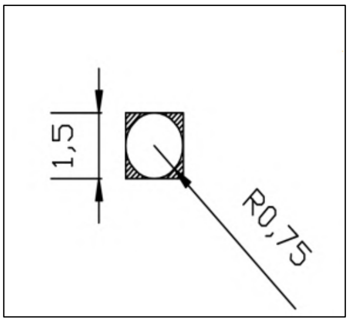

Fig. 2a. Raisebor technology for different diameters of the bit – R = 0,75 m

$$S_1 = a^2 = 2{,}25\ m^2;\quad S_2 = \pi R^2 = 1{,}77\ m^2;\quad S_1 - S_2 = 0{,}48\ m^2;\quad S_1/S_2 = 0{,}78 \tag{1}$$

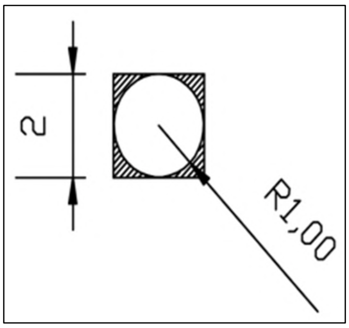

Fig. 2b. Raisebor technology for different diameters of the bit – R = 1,00 m

$$S_1 = a^2 = 4{,}00\ m^2;\quad S_2 = \pi R^2 = 3{,}14\ m^2;\quad S_1 - S_2 = 0{,}86\ m^2;\quad S_1/S_2 = 0{,}78 \tag{2}$$

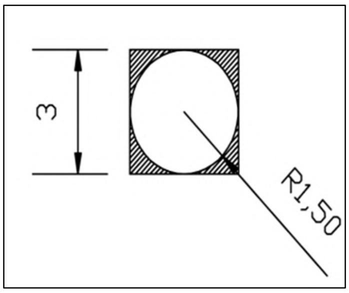

Fig. 2c. Raisebor technology for different diameters of the bit – R = 1,50 m

Optimisation of the losses and contamination when using the Raisebor technology

In order to ensure maximum recovery of the reserves using the Raisebor technology, different cases are considered for including the cutting head in ore bodies with thickness from 1.5 to 5 m (Fig. 2a, 2b, 2c, 2d, 2e).

$$S_1 = a^2 = 9{,}00\ m^2;\quad S_2 = \pi R^2 = 7{,}07\ m^2;\quad S_1 - S_2 = 1{,}93\ m^2;\quad S_1/S_2 = 0{,}78 \tag{3}$$

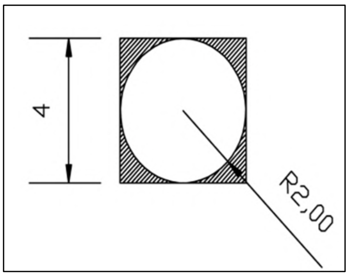

Fig. 2d. Raisebor technology for different diameters of the bit – R = 2,00 m

$$S_1 = a^2 = 16{,}00\ m^2;\quad S_2 = \pi R^2 = 1{,}77\ m^2;\quad S_1 - S_2 = 0{,}48\ m^2;\quad S_1/S_2 = 0{,}78 \tag{4}$$

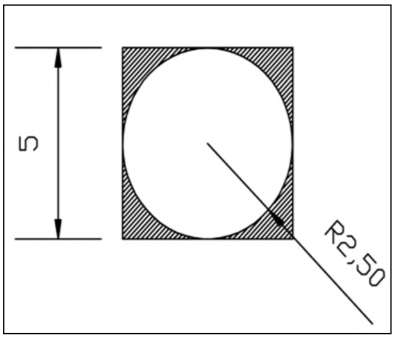

Fig. 2e. Raisebor technology for different diameters of the bit – R = 2,50 m

$$S_1 = a^2 = 25{,}00\ m^2;\quad S_2 = \pi R^2 = 19{,}62\ m^2;\quad S_1 - S_2 = 5{,}38\ m^2;\quad S_1/S_2 = 0{,}78 \tag{5}$$

The area ratios in the variant shown in Figure 2, S_2/S_1 for the five cases (a, b, c, d and e), show a mineral loss of 22% (the recovery ratio in this case is 0,78) or the contamination here is in the framework of the primary.

https://doi.org/10.1051/e3sconf/202128008021

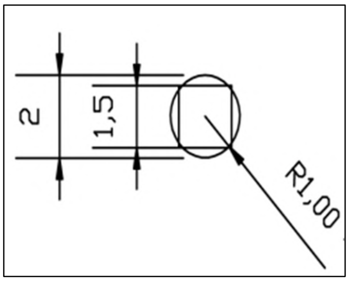

Fig. 3a. Raisebor technology with overlap of the contour

$$S_1 = a^2 = 2{,}25\ m^2;\quad S_2 = \pi R^2 = 3{,}14\ m^2;\quad S_2/S_1 = 1{,}39\quad S_1/S_2 = 0{,}72 \tag{6}$$

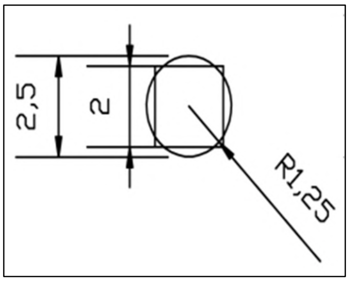

Fig. 3b. Raisebor technology with overlap of the contour

$$S_1 = a^2 = 4{,}00\ m^2;\quad S_2 = \pi R^2 = 4{,}91\ m^2;\quad S_2/S_1 = 1{,}23\quad S_1/S_2 = 0{,}82 \tag{7}$$

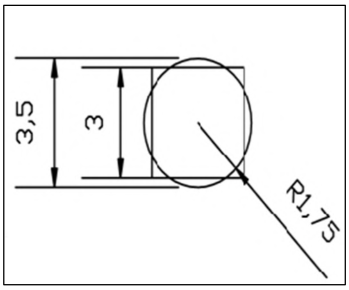

Fig. 3c. Raisebor technology with overlap of the contour

Table 1. Ratio diameter/thickness.

No	**Ratio diameter of recovery/thickness of the ore body**	**R_o %**	**Z %**
1	2,0/1,5 = 1,33	39	28
2	2,5/2,0 = 1,25	23	18
3	3,5/3,0 = 1,17	7	6
4	4,7/4,0 = 1,18	8	8
5	6,0/5,0 = 1,20	13	12

In order to reduce the losses, Figure 3 shows variants with an increased area of the cutting head relative to the ore body.

On Figure 3a with an ore body thickness of 1,5 m the diameter of the cutting head of the Raisebor machine is set to 2 m. In this configuration, the S_2/S_1 ratio = 1,39 or 39% contamination and S_1/S_2 = 0,72 or 28% losses.

When the thickness of the ore body is 2,0 m and the diameter of the cutting head of the Raisebor machine is 2.5 m, the ratios are S_2/S_1=1,23 and contamination of 23% and S_1/S_2=0,82 and contamination of 18%.

$$S_1 = a^2 = 9{,}00\ m^2;\quad S_2 = \pi R^2 = 9{,}62\ m^2;\quad S_2/S_1 = 1{,}07\quad S_1/S_2 = 0{,}94 \tag{8}$$

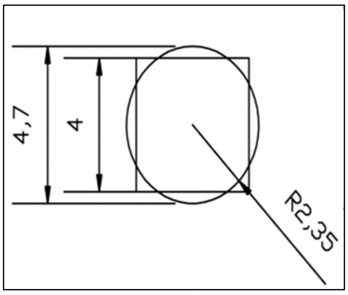

Fig. 3d. Raisebor technology with overlap of the contour

$$S_1 = a^2 = 16{,}00\ m^2;\quad S_2 = \pi R^2 = 17{,}34\ m^2;\quad S_2/S_1 = 1{,}08\quad S_1/S_2 = 0{,}92 \tag{9}$$

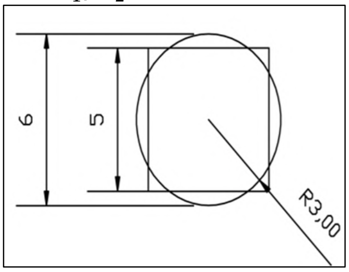

Fig. 3e. Raisebor technology with overlap of the contour

$$S_1 = a^2 = 25{,}00\ m^2;\quad S_2 = \pi R^2 = 28{,}26\ m^2;\quad S_2/S_1 = 1{,}13\quad S_1/S_2 = 0{,}88 \tag{10}$$

On Figure 3c with an ore body thickness of 3 m, the diameter of the cutting head of the Raisebor machine is set to 3,5 m. In this configuration, the S_2/S_1 ratio = 1,07 or 7% contamination and S_1/S_2 = 0,94 or 6% losses.

For an ore body thickness of 4.0 m and a diameter of the cutting head of the Raisebor machine of 4,7 m, the S_2/S_1 ratio = 1,18 or 8% contamination and S_1/S_2 = 0,92 or 8% losses.

When the thickness of the ore body is 5 m and the diameter of the cutting head of the Raisebor machine is 6 m, the S_2/S_1 ratio = 1,20 or 13% contamination and S_1/S_2 = 0,88 or 12% losses.

In order to reduce the damage from losses and contamination, it is recommended to observe the ratio S_2/S_1 from Figure 3c, which will determine the selection of the diameter of the cutting head of the Raisebor machine.

Raisebor technology using VCR method

This method for mining out the mineral reserves combines the drilling and blasting works (VCR method) with the Raisebor technology. [9, 10] Here again, we have the extraction of vertical levels (rises) from the ore body in a certain order, with the mined-out spaces being filled. This method is characterized by mining out the primary chambers by applying drilling and blasting works. It is important to note that the complete drawing of the extracted ore from each layer takes place after its complete blasting. Until the blasting of the last section (VCR method), part of the ore remains in the layer (rise), thus ensuring its safety without the need for its further support. After drawing the ores off from the primary chambers, they are filled with a paste-hardening fill to achieve sufficient strength of the chamber in order to open a secondary chamber next to the filled-in rock mass without leaving behind pillars.

The secondary chambers are mined out using the Raisebor technology and after their removal, they can be filled with both a paste hardening fill and a rock fill of sterile mass.

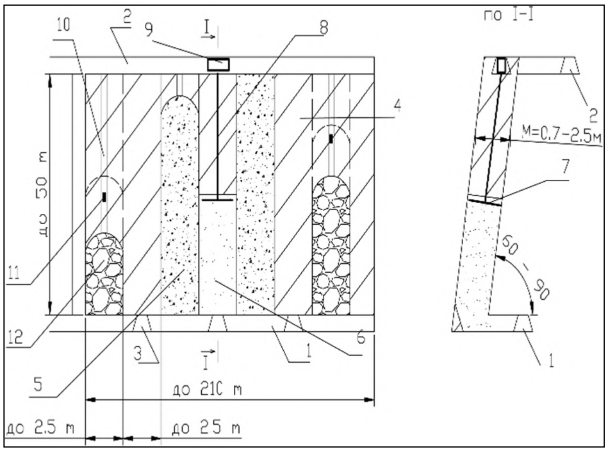

Fig. 4. Raisebor technology using the VCR method for extraction of mineral resources
Legend: 1 – haulage level; 2 – air drift; 3 – loading cut-off entries; 4 – ore body; 5 – paste-hardening fill; 6 – fines, extracted ore; 7 – cutting head; 8 – borehole; 9 – Raisebor machine; 10 – central borehole; 11 – VCR method; 12 – blasted ore.

The Raisebor technology using the VCR method emphasizes again on security, since during both production stages (VCR method and Raisebor technology) the processes are carried out without the presence of workers in the mining areas.

The geomechanical dimensioning will give the maximum open surfaces that can be naturally supported as well as the dimensions of the primary and secondary chambers. From here, the specific sizes of the mining blocks and their parameters should be determined, as well as the order for removing the reserves.

Continuous system for ore shrinkage and use of Alimak or KOV-25 monorail

This is a classic variant of the continuous system for ore shrinkage, but the specifics is that it has been redesigned for the purpose of applying a productive technique, elimination of the manual labour, removal of people from the mining areas, and its application in rocks with low strength indicators.

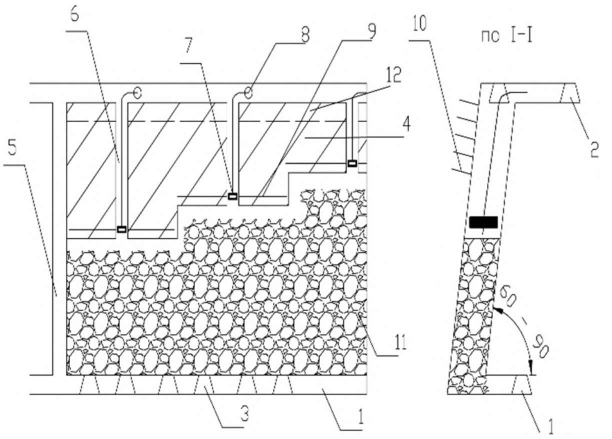

Fig. 5. Continuous system for ore shrinkage and use of Alimak or KOV-25 monorail complex
Legend: 1 – haulage level; 2 – air drift; 3 – loading cut-off entries; 4 – ore body; 5 – stope rise; 6 – cut rise; 7 – KOV-25 monorail complex; 8 – a winch for hoses of the monorail complex; 9 – drilling boreholes; 10 – rock bolts; 11 – retained ore; 12 – sheet pillar.

In the continuous system with ore shrinkage and use of Alimak or KOV-25 monorail complex, the mining operations are performed by cut rises with horizontally positioned blast holes (horizontal layers are blasted). The use of monorail ore mining complexes significantly increases labour productivity - hydraulic mechanization is applied. Through this configuration of the block and the extraction of the cut rises, the work safety is ensured, with the workers being in pre-fixed workings. Therefore, greater safety at work is achieved and the cost of ancillary processes is also reduced.

Another important point that should be noted in this technology is its application in the development of deposits with weak ores and host rocks. In the variant presented, the retained ore is used to support the host rocks. By the time the ore is completely blasted from the block, the amount of ore that has been drawn off must be just enough to absorb the blasted ore from the next blast layer. After the blasting is completed, the ore is drawn off in parallel with the filling of the store. The fill in this case may be dry rock fill with material; obtained from preparatory activities. Thus, we have constant support, eliminating the risk of unwanted movements in the rock mass.

Conclusion

These innovative mining technologies aim at developing deposits with complex geological, mining technical and geomechanical characteristics. The aim is to provide sufficient labour safety, increased productivity, reduced loss rates and impoverishment during the mining process.

The presented innovative production technologies meet these requirements.

The advantages of implementing and using them in a particular mining company can significantly improve the processes for the following reasons:

1. The developed innovative technology for mining of mineral resources (shrinkage method of mining, filling and setting of rib pillars – Alimak technology) allows for recovery of reserves without pillars and with minimal losses and contamination during the mining process.
2. With the application of the VCR - Raisebor technology for mining of mineral resources when developing complex-structured and geothermal deposits, we achieve a high level of system safety.
3. It is important to take into account the specifics of the deposit itself and the characteristics of the ore bodies, and based on this to select the number and type of mechanization, as well as the order of mining.
4. When mining with the Raisebor technology, it is not necessary for the obtained ore fines (the extracted ore) to undergo coarse crushing - it is possible to eliminate additional processes and ensure direct feeding of the ore to the mineral processing plant for further processing. This leads to a significant reduction in production costs.
5. When applying the VCR-Raisebor technology for mining there is a considerable positive effect because the obtained rock mass from the development stages is used for filling in the secondary chambers. Thus, the haulage of the mining mass (ore and sterile body) is facilitated and the volumes of the waste dumps for sterile rock mass are considerably reduced.
6. By developing innovative technologies for mining, in particular VCR - Raisebor technology, we create an opportunity for safe and secure development of deposits with complex conditions and characteristics, previously considered to be economically not viable.

Geomechanical models should also be developed in order to identify open surfaces that can naturally be supported. Thus, the specific parameters of the selected extraction technology such as height of levels, presence of sub-levels, dimensions of blasted layers, etc. could be determined.

Abstract. Spills of liquid radioactive material are reviewed as potential event that can be associated with release into the atmosphere. Existing approaches to radiological impact assessment for onsite as well as offsite of facility are presented. The example of using the actual Java version of the European RODOS system as prototype of the decision support system shows the general implementation of the analysis and preparation of initial data in order to model the radiological impact on the public, personnel and environment. Given the specifics of the occurrence of emergency scenarios of this type, features of atmospheric models application, description of the source term model, software integration features, ventilation task solving, completeness and format of the initial data required for radiological consequence modelling.

1 Introduction

Today, more and more often in order to model the radiological impact on the public, personnel and environment, decision support systems (DSS) for responding to nuclear and radiological accidents in real time are used (RODOS, ARGOS, HPAC, NARAC, etc. [1-6]). In addition to the primary tasks of the software, they are also applied in frame of emergency preparedness and planning, quantitative and qualitative analysis of possible scenarios taking into account the evolution and phenomenological stages of the events. This is primarily due to the wide range of data assessment tools both in terms of design capacity and in terms of simplicity of input and analysis of results. However, at present, a significant challenge for users of these DSS is to prepare a correct and complete package of initial data, in particular, source term data for each of the emergency scenarios under consideration. A large number of works are devoted to the development of separate special tools for creating information communication between source term assessment codes and radiological impact assessment systems. For instance developers of RASCAL have been overcome the obstacle related to fast source term assessments and simplified atmospheric modelling calculation that is fully justified by emergency response goals. However, the wide variety of potential emergency processes at nuclear power plants does not allow to create unified tool for preparing source term data that would cover all possible state of the affected facility.

An important area of nuclear power plant (NPP) safety analysis is the analysis of emergency scenarios associated with the spill of radioactive liquids [2]. In this paper, on the example of the use of JRODOS DSS, the basic requirements for the initial data in order to model the radiological impact in accidents are formed.

Worldwide there have been more than 30 significant accidents with spills of liquid radioactive materials at nuclear fuel cycle facilities for the last 60 years according to work [3]. Among there is the accident at research reactors, nuclear power plants, nuclear complexes, uranium facilities, pilot plants and chemical plants, etc.

Many special computer codes and methods are currently developed to assess, with sufficient accuracy, parameters of releases for various accidents at nuclear fuel cycle facilities (e.g. MELCOR computer code manual, US NRC for NPP). But, according to study [2, 3], these codes have some disadvantages and often require a large amount of input data, calculation time.

2 Analysis of previous publications

In the world practice of liquid radioactive material (LRM) - related events analysis assessments of the radionuclides distribution in the liquid-vapor system are based on the results of research (model and experimental data) in the context of normal operation, summarized in the standards and guidelines and standards of the US NRC such as NUREG-0016 [4], NUREG-0017 [5] on calculation of releases of radioactive materials in gaseous and liquid effluents. American National Standards ANSI/ANS-18.1-1999 [6] ANSI/ANS-18.1-2016 [7] have information on radioactive source term for normal operation of light water reactors. Among the latest studies in the direction of investigation on the intensity of evaporation from open surfaces of liquids [8-11] can be considered. Detailed description of the models integrated in actual decision support system JRODOS can be found in [12-14]. Studies on thermodynamic calculations ventilation and air conditioning, experimental data of heat and mass transfer during evaporation of the liquid with a free surface, thermodynamic properties of water and steam are collected in [5-20]. Information on existing toolkit for ventilation task solving, atmospheric dispersion modelling and dose projection such as ANSYS, Solid Works, OpenFOAM, MACCS, RASCAL, HOTSPOT is concentrated in [21-28]. The report [31] is focused on the results of the AVESOME project on source term uncertainties in decision support system context.

The publications [32-37] provide an information on existing procedures and format for data exchanging covering USIE platform, decision support systems and adjacent software.

The aim of the work is to complete the all stages of radiological consequences analysis for the group of events related to radioactive material spills using developed source term model taking into account requirement from side of actual decision support systems. It can be achieved due to solving of the next tasks:

• to give the definition of LRMs and describe the area of their application;

• to present proposed source term model;

• to put the light on integration of the developed model in context of actual approaches to ventilation task solving, atmospheric dispersion modelling and dose projection;

• to overview the uncertainties associated with source term modelling taking into account nowadays decision support systems and international projects conducting;

• to provide recommendation in selection of suitable atmospheric dispersion model on example of JRODOS system;

• to describe actual exchanging data format to approach the link between the stages of modelling.

3 The research results

3.1 Radioactive liquids

LRM are liquid solutions, which include impurities of radioactive elements (possibly bound in high-molecular complexes). The isotopic composition of LRM is determined primarily by the source of radioactive impurities. The main sources of LRM at nuclear power plants and nuclear complexes are as follows:

• primary coolant that is discharged for operational reasons;

• water that is used to back flush filters and ion exchangers;

• floor drains that collect water that has leaked from the active liquid systems and fluids from the decontamination of the plant and fuel flasks;

• leaks of secondary coolant;

• laundries and changing room showers;

• and chemistry laboratories.

LRM can be located: both under containment of NPP units and beyond (for example, in an auxiliary building). At Ukrainian power units, temperatures of the LRM can reach 320ºC (under pressure), fluctuations in the range from 40 to 100ºC are possible in pipelines and tanks, depending on the ways of discharge of radioactive effluents. Accidents involving LRM spills are characterized by intense heat transfer due to the evaporation of the liquid - the formation of vapor-aerosol forms, which are subsequently localized on the materials of treatment or localization systems - for example, on drops of a sprinkler system or on gas-aerosol filters of ventilation equipment. In case of disability of localizing systems, significant emissions of radionuclides can be considered due to the leakage from the emergency rooms.

The isotopic composition and activity of the LRM at the NPP varies greatly. E.g., the primary coolant and the water of NPP spent fuel pool holding with light water reactors makes a collection of fragments of forced separation ^{235}U and ^{238}U, isotopes of corrosion metals, neutron activation products, etc. Within an auxiliary building, radioactive media can be maintained for a long time and include only long-lived radionuclides (^{60}Co, ^{134}Cs, ^{137}Cs, ^{54}Mn etc.) in the isotope composition. A similar case is observed in research reactors. Heavy water, which is used as a moderator on liquid reactors, also has high activity due to the presence of tritium in it.

World nuclear complexes produce and process radioactive materials (e.g. NPP fuel, isotopic mixtures, industrial and medical sources). At nuclear complexes, as well as at nuclear power plants, reactor installations of different capacity are used. Nuclear complexes, chemical plants and research centers also work with the LRM. A distinctive feature of these enterprises in comparison with the NPP, in terms of the characteristics of the LRM used, is the large range of radioactive solutions involved in the technological processes of the enterprise.

At nuclear power plants and nuclear complexes, LRM are mainly aqueous solutions of decay products of nuclear fuel according to International Atomic Energy Agency (IAEA) safety standards and FSUE's materials [7]. Pilot plants and chemical plants may contain a full range of isotopes and solvents. LRM can be found on the site for processing the radioactive liquids.

Issue is a significant problem for radiotherapy medical hospitals. The problem is to analyze the emergency situations related to the special reservoir systems in the underground rooms of hospital (DTS systems – Decay Tank Systems containing ^{99m}Tc, ^{131}I, ^{18}F, shown in Fig. 1).

 https://doi.org/10.1051/e3sconf/202128009001

Fig. 1. DTS (Decay Tank Systems).

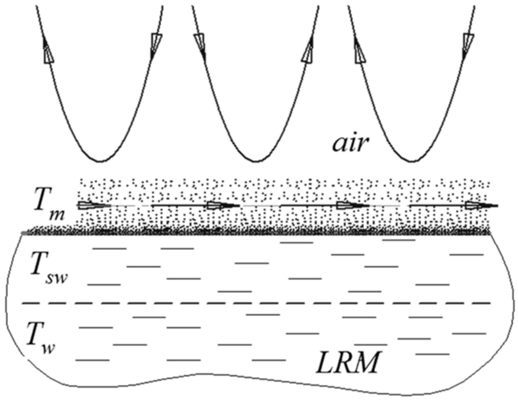

Fig. 2. The temperature layers near the surface of LRM.

3.2 Source term model

The proposed approach is based on the theory of non-stationary heat and mass transfer in surface evaporation of liquid heated below the boiling temperature.

The physical model includes: active liquid medium, steam-aerosol radioactive mixture (SARM), air of forced ventilation, airborne filters, and the floor of emergency area. The key aspects of the model are evaporation of liquid material, its removal with exhaust ventilation and partial trapping on airborne filters. It is considered that SARM is released to the environment after filters.

The model is developed to assess the radiation consequences in an accident with spill of LRM and describes the spread of radioactive material by two consecutive ways: releases within the emergency area and further transfer of SARM into the atmosphere. In this paper, we focus on the relationship of these pathways and study the process of evaporation as special one for accident with spill of LRM (Fig. 2).

To solve the problem of unsteady LRM evaporation, four balance differential equations were written to relate the main parameters of LRM and air space of area over time.

$$\begin{cases} \dfrac{dm_w}{dt} = -\beta_{sw}\left(p_{sw} - p_m\right)S - G_d \\ \dfrac{dm_a}{dt} = \beta_{sw}\left(p_{sw} - p_m\right)S - G_V \cdot \dfrac{m_a}{V} \\ \dfrac{dm_q}{dt} = G_V \dfrac{m_a}{V}\left(1-\psi\right) \\ \dfrac{dT_w}{dt} = -\dfrac{r_w\beta_{sw}\left(p_{sw} - p_m\right)S + kF\left(T_w - T_f\right)}{c_p m_w} \end{cases} \tag{1}$$

where m_a – current mass of SARM in air of the area, *kg*;

G_d – flowrate of LRM through the drainage channel (it also includes the volume of LRM leakage from the area), *kg/s*;

V–air volume in the area, m^3;

G_V – flowrate of involved air of forced ventilation (this parameter includes SARM leakage through the gaps or clearances in walls of the emergency area) m^3/s;

ψ – coefficient of filtration (efficiency of filtration);

m_q –mass of released SARM into the atmosphere, *kg*.

Functions $\beta_{sw}(T_{sw})$, $p_{sw}(T_{sw})$, $p_m(T_m)$, $r_w(T_w)$ and $c_p(T_w)$ are polynomials. They are compiled according to [8-12].

In model, the performance of forced ventilation unit is determined by the flowrate of involved air. After the exhaust ventilation pipe, SARM partially settles on filters. This phenomenon accounts for the coefficient of filtration. It determines the relative amount of SARM that is deposited on the filter material. SARM further passes through the ventilation stack into the atmosphere.

Another method to confine LRM is to drain the spilled liquid by drainage pumps or by gravity. This process is characterized by the flowrate of LRM through the drainage channel.

The partial removal of radioactive substances from the liquid by evaporation depends on physicochemical properties of radioactive impurities and the solvent.

This system of nonlinear differential equations includes polynomial functions. Using the Mathcad sphere for solving the system of equations provides the desired functions in matrix form (the values of the functions at particular moments of accident).

Average activity concentration of the radionuclide in the area air A_{air} (Bq/m^3) is given by the formula

$$A_{air} = \frac{A_w}{V} H \cdot m_a \tag{2}$$

The ultimate objective of the model is to determine the dynamics of LRM evaporation, SARM activity in the air space and the integral release of radioactive substances into the atmosphere. The mass fraction of a radionuclide in the release relative to its original content in radioactive liquid is commonly used in practice:

$$q = \frac{A_w}{m_0} H \cdot m_q \cdot 100\% \tag{3}$$

where m_0 –initial mass of LRM, *kg*

This value is used as an input parameter for the assessment of doses to the public from atmospheric release.

3.3 Ventilation task solving

Using such products as ANSYS software [13], OpenFOAM [14], SolidWorks [15] additionally studies the impact of forced ventilation system on the velocity of the underlying layer supply air. The velocity values found

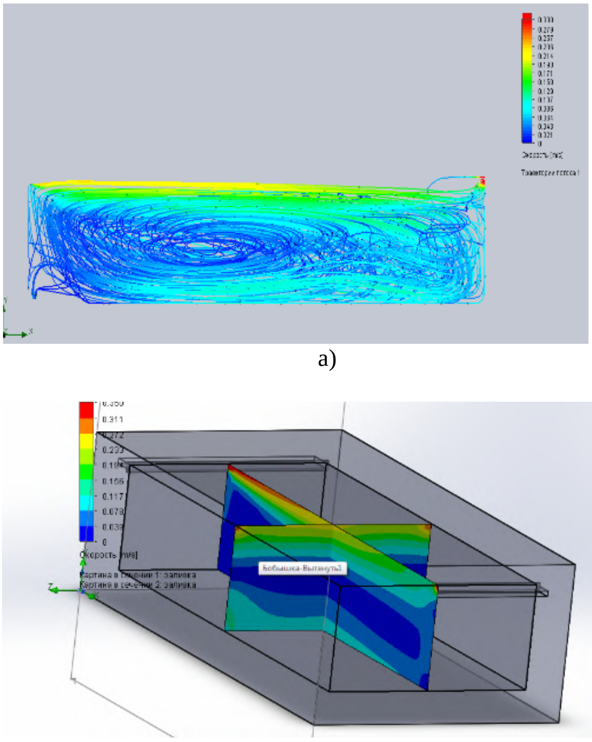
 https://doi.org/10.1051/e3sconf/202128009001

are used to clarify the surface temperature of the liquid according to [8-12]. The results of the impact analysis revealed that the speed the incoming flow has a significant effect on the evaporation intensity, as the consequence - on the ejection. Therefore, one of the prerequisites for the preparation of initial data and boundary conditions for the model is a preliminary ventilation solution tasks within the established technological parameters.

Using the SolidWorks software, the influence of the ventilation system flow on the velocity of the underlying inlet air layer was investigated (Fig. 3-5).

3.4 Integration in atmospheric dispersion and dose projection tools

Based on the results of the mathematical model with a view to further determination of radiological impact on the workers, public and the environment the environment can be used analytical methods and software tools (Table 1).



a)

b)

Fig. 3. Air flow fields SolidWorks simulation (G_V=0,75 m^3/s): flow trajectories (a), velocity fields (b).

Real-time On-line Decision Support System for off-site emergency management (RODOS) provides consistent and comprehensive information on radiological situation development, the extent and the benefits and drawbacks of emergency actions and countermeasures, and methodological support for taking decisions on emergency response strategies. Main users of the system are those responsible at local, regional, national and international levels for off-site emergency management.

Fig. 5. Air flow fields SolidWorks simulation (G_V=1,5 m^3/s): flow trajectories (a), velocity fields (b).

RODOS has the most diverse collection of dispersion models, with one of each type of dispersion model incorporated into the code: Lagrangian (RIMPUFF, DIPCOT and LASAT), Eulerian (MATCH). Additional decision aiding components can facilitate the ranking and selection of alternative options using decision analysis procedures. Thus, RODOS system allows real-time operation for offsite emergency management as well as applications for exercise, preparedness, and planning.

Table 1. Font styles for a reference.

Model outputs	**Workers exposure**	
	internal	external
Array of air concentrations in emergency room Av(t)	• Analytical base and methods (NRC, ICRP, UNSCEAR [16]); • Dose conversion factors FGR-11/13, EPA [16]	• Analytic base (NRC, EPA, ICRP) + dose from skin exposure (α and β); • MICROSHIELD, ISOCSR (+ dose from equipment and spill domain) [16]
	Public exposure and environmental contamination	
Array of time-integrated activity released into the atmosphere (source term) Q(t)	• RODOS: RIMPUFF atmospheric dispersion model with 10-min. time step + FDMT [17]; • ARGOS: complex terrain ADM, dose projection module (any other DSS); sophisticated models for short range (CFD-, LES-modeling); • simplified Gaussian models HOTSPOT [18], RASCAL (INTERRAS) [19]; NRC MACCS code (probabilistic analysis tool) [20]; • GENII, RESRAD, PAVAN, ARCON 96, XOQDOQ (RAMP codes family)	

RODOS is user-friendly and has an intuitive graphical user interface. The integration of GIS functionalities enables graphical representation of results. JRODOS features and tools allow the adaptation of the system to national conditions and user preferences.

In 2013 in the frame of European Commission project INSC U3.02/08 (UK/RA/08) Java-based Decision Support System JRODOS was installed in SNRIU's Information and Emergency Centre (IEC). At the Rivne NPP, the RODOS system was implemented in 2012. The RODOS system was installed at the central post of the automated radiation monitoring system (ASRM). ASRM equipped with powerful meteorological complexes that is very important for the use of RODOS. Data in special formats from four ASRM meteorological complexes, from radiation monitoring points and mobile laboratories are transmitted to RODOS via software that ensure interface of ASRM with RODOS. On October 8-10, 2013, the training course “Program system JRODOS – new multiplatform version of the European DSS for the off-site nuclear emergency management – RODOS” was held in Kyiv. Experts from SNRIU, SE NNEGC “Energoatom”, State Emergency Service of Ukraine, Ukrainian Hydrometeorological Center, State Enterprise “State Scientific and Technical Center for Nuclear and Radiation Safety”, Khmelnytskyi NPP, Rivne NPP, Zaporizhzhia NPP were invited to participate in the training.

On October 11, 2013, testing was carried out on the RODOS software system, which was already installed at the IEC of the SNRIU. The testing was performed with participation of technical experts of the Karlsruhe Institute of Technology (KIT). The testing addressed, inter alia, issues of connection of the RODOS to the ASRM system and the system of operational weather forecasting for the Rivne NPP. At the Rivne NPP, RODOS uses global meteorological data covering the entire globe and predicts the movement of air masses in case of radiological accident, "dirty" bombs and other nuclear emergency scenario. Due to the cooperation with the Ukrainian Center for Environmental and Water Projects, which at one time developed the hydrological model of the river Stir for the RODOS system, and reprogrammed the RODOS system into the JAVA programming language (this version is currently used by European and Asian users), Rivne NPP installed software which allows to independently calculate the weather forecast for almost any territory of the Earth. The calculations are based on input from the US National Oceanic and Atmospheric Administration.

Today, RODOS system is operated by SNRIU's IEC, UHMC, State Emergency Service of Ukraine, Khmelnytskyi NPP, Rivne NPP, Zaporizhzhia NPP, South Ukraine NPP and State Agency of Ukraine on Exclusion Zone Management.

Since 2017 all Ukrainian JRodos users are supported by numerical weather prediction provided by Ukrainian Hydrometeorological Center (UHMC) and The Institute of Mathematical Machines and Systems Problems of the Ukraine National Academy of Science (IMMSP NASU). SNRIU's IEC has access to 96-hour NetCDF files WRF result and DMI-files covering the whole territory of Ukraine in real time (Fig. 6-7). Since 2019, more precise NWP are available separately for southern and northern parts of Ukraine.

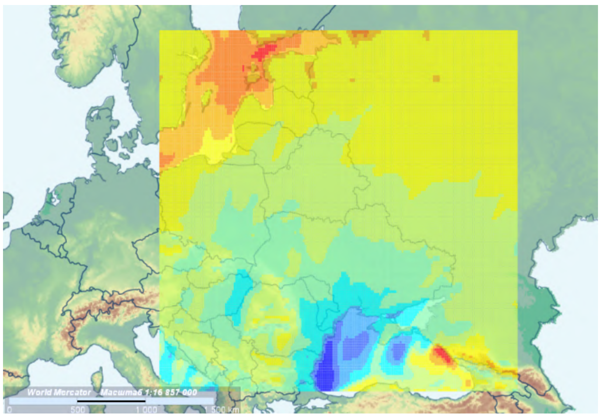

Fig. 6. NetCDF file – the whole territory of Ukraine and neighboring countries: duration of prognosis – 96 hrs, step of updating – 6 hrs, spatial resolution – 0.15°.

JRodos-DataSupplier as an application to JRODOS system is installed in SNRIU’s IEC for an automatic receipt of fresh numerical weather predictions for all the territory of Ukraine, parts of adjacent countries and for some territories around Ukrainian NPPs and Chornobyl Exclusion Zone. SSTC NRS experts have an access to sftp-server with numerical weather predictions data. Some additional weather information or extended numerical weather data can be required from Ukrainian Hydro-meteorological Center (UHMC).

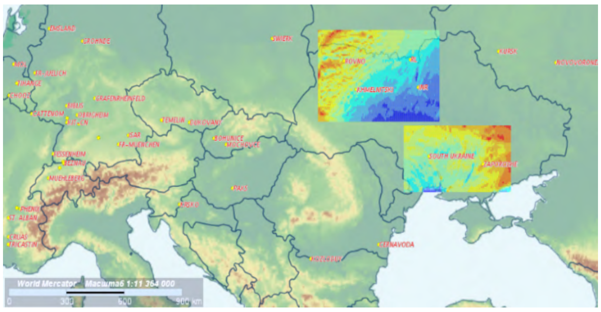

Fig. 7. NetCDF files covered Rivne NPP, Khmelnytskyi NPP, Chornobyl NPP and South Ukraine NPP, Zaporizhzia NPP: duration of prognosis – 96 hrs, step of updating – 6 hrs, spatial resolution – 0.05°.

HIRLAM files for MATCH model has the spatial limitation as for NetCDF files.

The system includes a number of atmospheric models that make it possible to simulate the motion of a radioactive cloud and atmospheric diffusion at different scales relative to the source term (Table 2). In [2], it was determined that the total amount of activity released during accidents involving the spill of liquid radioactive media is insignificant compared to severe accidents at nuclear power plants and leads to significant contamination of nearby areas in the path of radioactive cloud propagation. In the Table 2 shows the models of atmospheric transport by priority in order to solve the problem of estimating the radiation impact on the population for events with the spill of radioactive liquids.

Atmospheric dispersion modelling provides a lot of requirements be taken into ac-count in source term modeling for event associated with LRM. E.g., local scale model chains of DSS JRODOS allow to use several ways to fill in input parameters window. Most of them are used to bind to the initial activity (the number fission products) of the NPP reactor core. However, for cases where source term is undetermined by de-fault user library, such as wildfire in the contaminated forest, unintentional melting sources of ionizing radiation, emissions of pharmaceuticals and etc., it is possible to enter initial parameters at some number of time intervals (e.g., in the versions of DSS JRODOS 2017, 2019 - up to 128 time steps).

It is important to notice in most cases territory affected due to LRM spills are cordoned in near range scale. So scaling effects related to it (e.g. building wake effect shown in Fig. 8) should be considered in atmospheric dispersion modelling.

Moreover, selected time step of source term should be harmonized with both spatial resolution of modelling and time resolution of numerical weather data. Given the resolution of numerical meteorological data for the model RIMPUFF, a minimum results time step that correlates with local sensitivity JRODOS atmospheric dispersion models and meteorological pre-processor is 10 minutes. Such step allows to provide an accurate calculation in near and middle range up to 21 hours. In the case of input of stationary meteorological fields (manually) time step of the input data the source term needs additional adjustments in accordance with the minimal time step of meteorological data.

Practice of sensitivity analysis of such primary ones atmospheric propagation results as the integral radionuclide concentration in the ground layer to the general JRODOS initial data package in [21, 22], shows that the main problem in modelling is uncertainty in the source term. Such data include power, chronological parameters, speed, temperature, geometric height, radionuclide composition and physic-chemical forms of emission over time. For import source data from the outside or export to a file, the JRODOS system uses xml-formats.

3.5 Uncertainties issue

The practice of sensitivity analysis of such primary results of atmospheric propagation as integral concentration of radionuclide in the surface layer of air to the general package of initial data of JRODOS system shows that the main problem in modeling is uncertainty in initial data on source term. Such data include power, chronological parameters, velocity, temperature, geometric height, radionuclide composition and physicochemical forms of emission over time. To import source data from outside or export to a file, the RODOS system uses XML-formats.

Table 2. JRODOS atmospheric dispersion models.

№	Name	Type	Calculation distance, km	Resolution in the results tree (minimal), м	Meteorological data format	Remark
1	RIMPUFF (RIsø Mesoscale PUFF model)	mesoscale Lagrangian puff model	<800	50x50	user-defined / NWP data NetCDF	takes into account the initial parameters of the atmospheric dispersion; marked by stable calculation
2	LASAT (LAgrange Simulation of Aerosol Transport)	Lagrangian particle model	<800	50x50	user-defined / NWP data NetCDF	approved methodic approach of doses assessment is used
3	DIPCOT (DIsPersion over COmplex Terrain)	Lagrangian particle model	<800	50x50	user-defined / NWP data NetCDF	takes into account the complex terrain, however, does not take into account the initial parameters of atmospheric dispersion

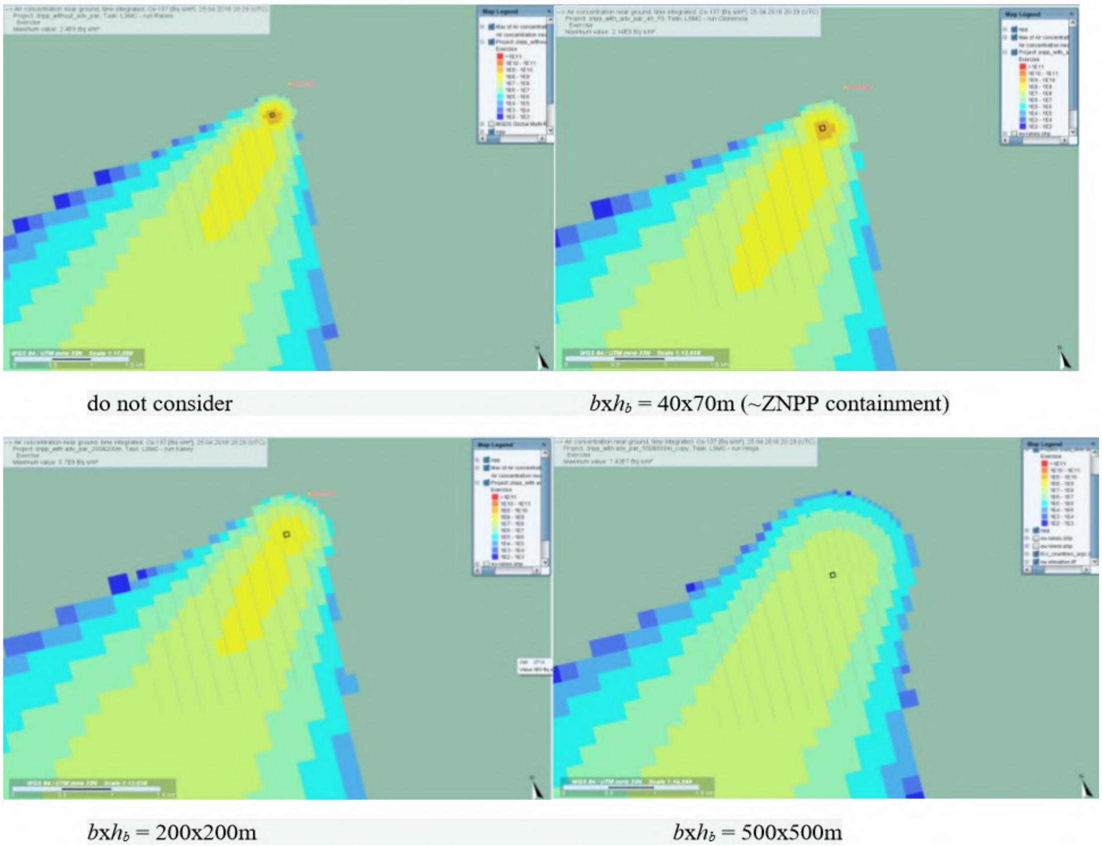

Fig. 8. NetCDF files covered Rivne NPP, Khmelnytskyi NPP, Chornobyl NPP and South Ukraine NPP, Zaporizhzia NPP: duration of prognosis – 96 hrs, step of updating – 6 hrs, spatial resolution – 0.05°.

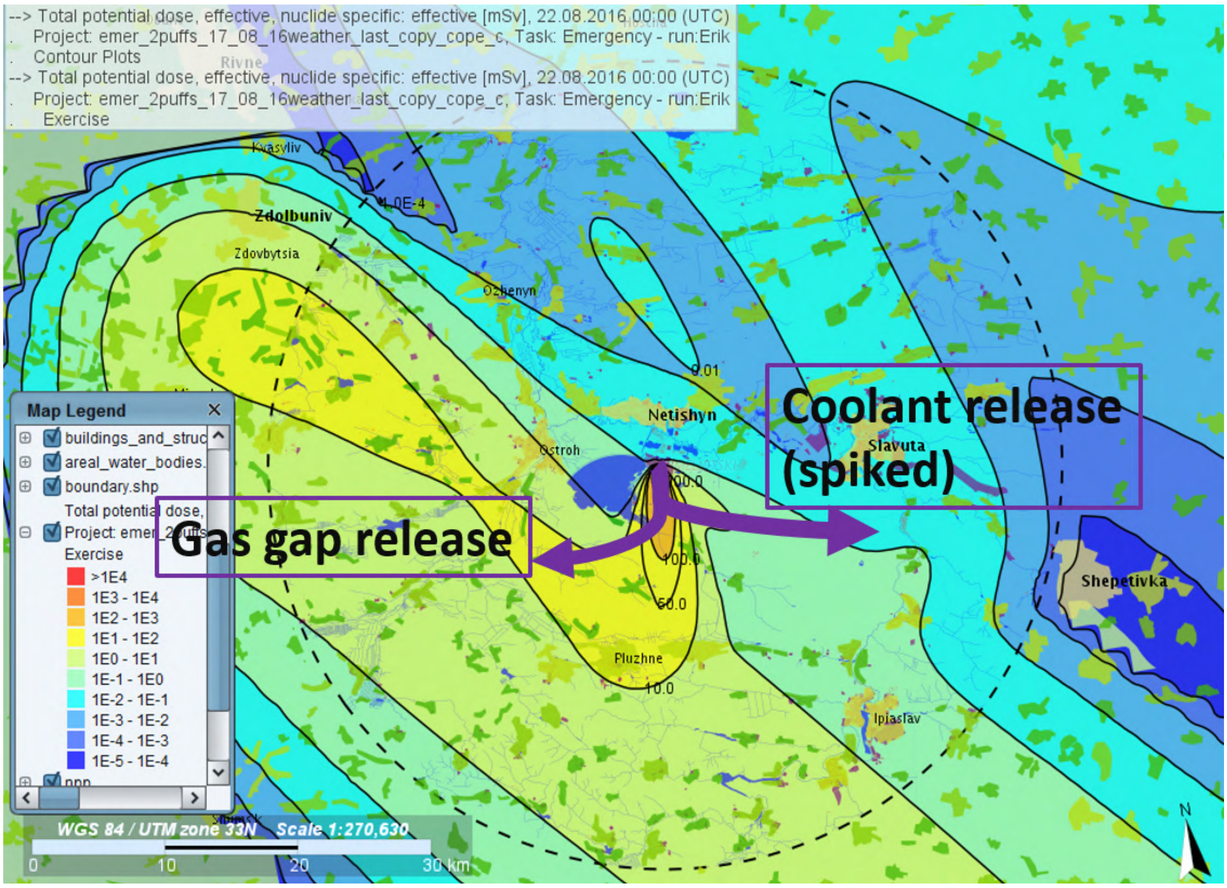

Fig. 9. Effective dose patterns from coolant and gas gap puffs (45-min difference between 2 release stages), mSv.

The main task of modeling the emission source is to obtain a set of arrays of output parameters depending on the time variable using separate analytical and / or numerical means. However, a preliminary analysis of existing industry and industry-wide computer tools [2, 3] showed that modern modeling tools in this direction have a number of significant shortcomings that do not allow it to be used for quantification of emission sources in spills of liquid radioactive.

In frame of FASTNET project experience of more than 20 countries was analyzed. The main output of the project is an investigation in the area of qualitative characteristic of source term – resolution in time. Taking into account spatial and temporal resolution of numerical weather predictions used in Europe countries, FASTNET group recommend the use of 15-min intervals in source term.

Fig. 9 shows a case of unstable meteorological conditions within 30-km surveillance zone of Khmelnytskyi NPP in summer 2016. This is an experience of SSTC NRS JRODOS calculation on NWP-data of July 11, 2016 (1-hr, 0.15º resolution). Source term was modelled for reactor core accident according to with consequent phenomenological steps coolant (spiked) release, gas gap release, and start of early in-vessel phase.

Practice of regular calculations demonstrates significant uncertainties in conjunction «source term – NWP-data». Under unstable meteorological condition with complex patterns of integrated concentrations, using of more than 15-min. source term intervals can lead to crusual impact on radiological consequences results.

JRODOS users can operate pre-estimated source terms data. Source term library filling can be specified by requirements to source term files taking into account meteorology data resolution. Uncertainties of the source term on the prediction of atmospheric dispersion of released radioactivity involve both the amounts of radionuclides released and the temporal evolution of the release.

In AVESOME project [23], a methodology is developed which can handle both a few-member source-term ensemble and a large ensemble spanning all possible releases. The AVESOME methodology will work well with the Rapid Source Term Prediction (RASTEP) system, which provides a set of possible source terms with associated probabilities based on pre-calculated source terms. The methods, which are being developed in AVESOME, allows for efficient real-time calculations by making use of scaling properties in the equations governing the release and the atmospheric dispersion of radionuclides. Accordingly, the computer-resource demanding calculations should be carried out at the high-performance computing (HPC) facilities available e.g. at national meteorological services, whereas less demanding post-processing should be carried out at the computer hosting the DSS.

A protocol is suggested for interactive communication between the DSS and the HPC facility enabling the requests from the DSS user for long-range atmospheric dispersion model calculations. It is based on an existing operational protocol extended with the capability of simultaneous handling of a number of source-term descriptions, including a full source-term ensemble.

3.6 Data exchange

IRIX is a technical standard developed by the IAEA in cooperation with experts from Member States and the European Commission (EC). The standard is designed to enable the development of interoperable systems and solutions for exchanging emergency information and data between organizations at both national and international level during a nuclear or radiological incident or emergency. A principal concept in the IRIX Format is the IRIX report. Any information exchanged in the IRIX Format must be packaged as the IRIX report according to [24-26].

The IRIX report represents a message containing emergency related information and data, and/or requests for such information or data, sent from one organization to one or more other organizations. The IRIX report encompasses information such as basic information about the event (date and time of event, location, etc.), information about the status of the nuclear facility or radiation source involved, information about any releases of radioactive material to the environment, information on protective actions taken or planned to protect the public, and radiological monitoring data. The report covers information that is of immediate use to authorities for taking decisions on protective actions for the public, but also more detailed information and data that can be used for improving the assessment of the emergency situation and the subsequent decision making. The IRIX report structure supports the key categories of information to be exchanged internationally under the terms of the Convention on Early Notification of a Nuclear Accident. The use of the IRIX Format is, however, not limited to this application.

IRIX is an open format based on the Extensible Markup Language (XML), which makes it both machine- and human-readable. It should be used to exchange radiological information between IAEA and RANET teams, or between any other two (or more) assisting parties, during a nuclear or radiological emergency. The IAEA has developed the IRIX format as the recommended standard to exchange information among emergency response organizations at national and international levels during a nuclear or radiological emergency. The standard covers the data content, the data format (XML), and the system interface specification. Data can include status information about a nuclear installation, information about any radioactive releases to the environment, information on protective actions taken or planned by affected countries, and environmental radiation monitoring data. Regarding to [26-28], the system interface specification (or web-service specification) enables organizations to interconnect their emergency information systems to automate their information exchange in an emergency.

4 Conclusions

In the paper general context of radioactive liquids events in modelling area is presented. For the first time source term model for radioactive liquids spills taking into account technological premises and adjacent environmental has been proposed and developed. This model, unlike other models, takes into account the parameters of the radioactive liquid composition and the design conditions of their storage.

Possible ways of software integration of the developed mathematical model into atmospheric dispersion modelling and dose projection toolkit, taking into account the requirements of the adjacent radiological impact assessment tool and the specificity of liquid radioactive accident spill, is proposed. It solve the problem of complex radiological estimation for events including LRM. The developed model can be applied as useful tool of source term preparation in the case of LRM spill in advance as a well as in real time with a reasonable degree of conservatism. It allows to provide an adequate assessment of the radiological consequences for the set of initial conditions of accidents with spills of LRM in areas with forced ventilation.

IRIX format has been considered as an effective data exchange tool to perform the initial data or radiological consequences results in modelling area.

Abstract. We have offered the investigations aimed at the design of eco-efficient technologies during oil and gas producing sites life cycle. The authors have conducted the analysis of conditions causing environmentally hazardous situations at oil and gas producing sites. We have established the necessity of quick maintenance of operation during emergencies that makes it possible to reduce material costs and environmental pollution. The increase of environmental safety in the process of winding up oil and gas wells emergencies that took place as a result of catching drilling string or some other pipe is crucial. We have analyzed different ways and various structural designs of the devices for pipe unscrewing from caught strings. We have established the ways of negative environmental impact reduction in the winding up emergencies at operating as well at stack oil and gas rigs. The recommendations regarding the structural design of the device are given. The device design is patented and the prototype model of the device is designed and manufactured. The device functions as the transformer of clockwise drilling string rotation into anticlockwise rotation of fishing tools. We have highlighted the positive effects after the implementation of the given device. We have noted the importance of innovative technologies design as well as the importance of forming adequate response skills during emergencies when wellsites are being constructed. The technical solutions and recommendations we have introduced make it possible to prevent negative environmental impact and reduce resource flows at different stages of wellsite life cycle.

1 Introduction

The activities of oil and gas producing sites affect the environment, especially during some emergencies. The complexity of the issue lies in the fact that those oil and gas producing sites may be located close to protected or recreational areas [1]. Alongside with this negative effects may last for a long time and be dangerous to the environment [2], which calls for the search of innovative technical solutions, as well as alternative energy sources development. [3, 2] When industrial objects function in their normal mode it has a set of consequences: sickness rate increase, disturbance of natural environment functioning, resource capacity influence. There is also the economic constituent of the given issue [4, 5]

2 Analysis of previous publications

The environment within the boundaries of oil and gas producing sites is intensively affected. Saksonov M.N. and others point out the environmental changes in the process of man-caused impact of oil and gas extraction [6] The most dangerous are the emergency situations that are the most unpredictable ones in terms of economic and environmental consequences [7, 8].

There is a set of conceptual approaches for maintaining environmentally safe production process at oil and gas producing sites [9, 10, 11]. The important measures that make it possible to prevent environmental pollution and to cut the material costs – are modernizing equipment [2, 12, 13]. Environmental aspect of modernizing equipment includes cutting expenditure resources during equipment manufacturing as well as during man-caused operations with the use of this equipment.

The investigations aimed at the increase of equipment operation responding for emergency drillstring jamming (e.g. pumping compressor, casing) in the wells are topical, because the removal of emergency situations demands unscrewing the pipes from the jammed part of the string, which is accompanied by economic losses, namely material and power ones. The removal time is also influences economic losses and environmental safety. If the wellsite is abandoned or put out of commission it is also necessary to unscrew the pipes. This calls for the necessity to develop environmentally efficient methods of prompt emergencies removal.

3 The research results

3.1 The triggering events of environmentally hazardous situations at oil and gas producing sites

Emergencies that take place at oil and gas complex, namely at wellsite are the cause of a set of environmental issues. These issues that are typical to oil and gas complex have been investigated in academic papers [14, 15, 16, 17].

Technological processes of oil and gas extraction are characterized by multicomponent structure of working environment (drilling fluids, extracted fluids and other technological fluids), that may contain toxic components and be flammable. These factors when summed up, pose a certain threat for the staff and contiguous territories with their inhabitants. One of the high risk-bearing factors is also the high level of technological equipment wearing. The processes that take place in this equipment cause its intensive degradation in long-term operation conditions and at presence of aggressive media that in their turn increase the environmental risks during oil and gas extraction. Equipment wearing is a serious risk factor that makes it difficult to solve environmental issues at oil and gas extraction complex.

In oil and gas extraction industry apart from specified and accounted pollution sources there may emerge unpredictable emergency conditions resulting in substantial costs of resources for primary operation conditions restoration, environmental pollution is noted and hazard to staff's health arises [18, 19, 20]. Different stages of oil and gas industry life cycle fig. 1 affect the environmental impact of different levels of intensity and damage [21]. Thus, we my single out specified emissions, caused by provided technological processes. Environmental hazards estimation if the impacts alike at are described at different stages in academic papers [22, 23, 24, 25]. The most important stage of environmental impact estimation is monitoring of different environments [26, 27, 28].

Modern geophysical investigation methods make it possible to collect information about equipment condition and wellsite geological profile which helps to evade significant environmentally hazardous consequences with occurrence of environmentally hazardous substances [29, 30]. The combination of methods for environmental monitoring and equipment condition makes it possible to reduce the risk of environmentally hazardous cases. But emergency conditions that may occur during operating conditions should be removed within the shortest possible time. Thus, taking into account all the factors mentioned, the aim of this article is to develop the effective tool for unscrewing pipes within a wellsite with increased operation reliability and enhanced technological possibilities. The main idea of innovative tool development is to reduce time costs for removing emergency conditions that makes it possible to increase environmental safety level of the wellsite construction process and oil and gas extraction.

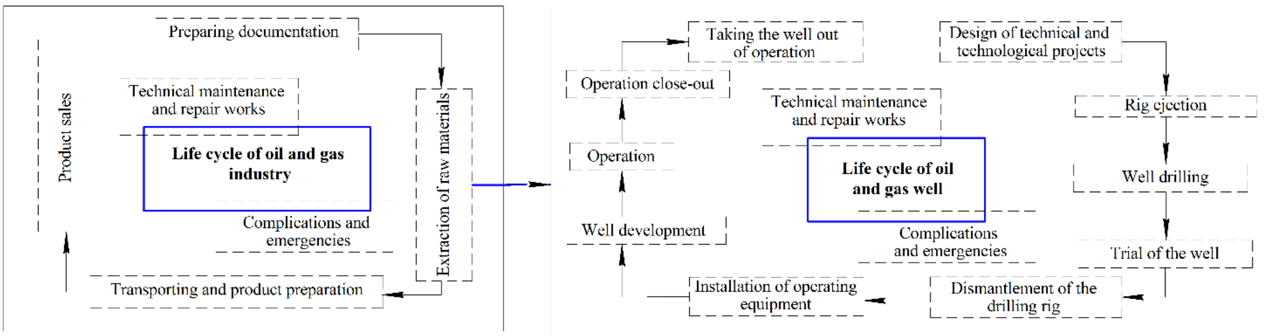

Fig. 1. The chart of life cycle of oil and gas well in the system of oil and gas extraction industry [21].

3.2 The analysis of equipment constructions used for unscrewing pipes in the wellsite

As we have already noted above, in emergency conditions it is crucial to select the technology that will make it possible to eliminate faults promptly and efficiently. Taking this into account we have analyzed the existing devices for unscrewing pipes in the wellsite.

We are aware about the device for unscrewing pipes in the wellsite [31], consisting of a case, upper (master) and lower (driven) pipes with pipeline thread for joining it to drilling strings and fishing tools respectively. This device also has an anchor knot (anchor) with fixing elements in the shape of elastic chambers and reverse gear in the shape of bevel gearbox. The master device also has the device for anchor knot actuation, consisting of throttling nut, screwed at the lower end of upper (master) shaft. The device sets the anchor knot going by means of feeding flushing liquid into fishing string, which at the cost of change of pressure in the throttling screw restores required pressure in the anchor knot and penetrates elastic chambers, broadening them for contact with the internal part of casing string.

The essential limitation in the use of this device is the low reliability of device fixture by flushing liquid pressure and also the use of elastic chambers as fixture elements as they may be corrupted when the device is lowered into the wellsite.

The next device for unscrewing pipes in the wellsite

https://doi.org/10.1051/e3sconf/202128009002

[32] is the one that has hollow cylindrical case with the pipe thread placed at its lower part. The hollow shaft with the screw is located at the upper part to be joined to the fishing string. The anchor knot (anchor) is also present with fixing telescopic parts and reversing gear in the shape of pull chain interacting with the rim, placed at the inner surface of hollow cylindrical case of the device. The driven device also has the mechanism for anchor knot activation which consists of throttling screw, placed at the lower end of hollow shaft. The device sets the anchor knot going by means of feeding flushing fluid into fishing strings that at the cost of change of pressure in the throttling screw causes pressure in the anchor knot case on fixture elements.

Among the drawbacks of this device are the following:

• reversing gear low performance index, that makes it impossible to create sufficient moment of force, necessary for screwing fishing instruments with further pipes unscrewing. It happens due to sufficient pull chain dragging against outer cylindrical case surface of anchor knot;

• technological complexity of the design of separate elements of the device, namely, the rim on the inner case surface.

There is also the device for unscrewing pipes in the wellsite [33] that has hollow cylindrical case with the left reducing coupling located at the lower part with the right coupling device located at the upper part of the device. The anchor knot with fixture elements is also present, the reversing gear in the shape of planet gear, consisting of master hollow shaft-gear and planet carrier placed so that it is possible to interact with shaft-gear and the rimmed surface, performed on inner cylindrical surface of the device’s case. The shaft-gear device is placed at the roller bearing with the ability to rotate towards the case of the device and with the presence of anchor knot activation device.

The peculiarity of this device is the fact that the anchor knot fixture elements are designed in the shape of slips that have the ability by moving along pyramidal facets of the case of the device radially to interact by their working hard-alloy surface with the inner wall of the casing string, ensuring reliable fixture of the device.

Among the drawbacks of this device are the following:

• the use of slips in the anchor knot, placed at bearing slides such as “dovetail” significantly complicates the device configuration and decreases its operation reliability. It is caused by the penetration of abrasive particles that are abundant in the wellbore of that direction, which may result in jamming and, respectively – device nonoperation;

• the use of the wedge mechanism in the anchor knot significantly limits the range of radial slips advancement which does not ensure the possibility to use the driven device in casing strings of different diameter without the replacement of fixture elements.

In order to unscrew the stuck (jammed) drilling string two basic methods are used [34, 35]. The first one – is the use of the string with double-sided screw, the second one presupposes the use of a special device that turns clock-wise rotation of the given drilling string into anti-clockwise rotation of the fishing tool (taper tap, collar socket, tubing catch, etc.) connected to the jammed part of the string.

The first method, the one that is using pipes with anti-clockwise screw has the following drawbacks:

• the necessity to purchase or lease that kind of a string if it is operating at a different wellsite, or manufacturing the needed amount of them, which causes additional expenses;

• transportation expenses of a big number of pipes;

• the replacement of the existing string of pipes with that one with anticlockwise screw is a labor-consuming process;

• environmental pollution with exhaustion gases and petroleum products during transportation and double replacement of pipe strings;

• time-consuming preparatory works, associated with the expansion of storage space and storage of a big amount of pipes and increase of expenses, that has a negative effect on the environment.

Taking into account all the above-mentioned the given academic paper is mostly concentrated on the second method – the use of a special device for turning clock-wise rotation of the given drilling string into anti-clockwise rotation of the fishing tool. In our case it is obvious that the above-mentioned drawbacks are neutralized by using of anti-clockwise pipes.

3.3 The design of innovative device construction for unscrewing pipes in the wellsite

The purpose of design of a new efficient device is to create a device construction for unscrewing pipes in the wellsite with high performance output and improved technological possibilities, achieved at the expense of addition of anchor knot fixture elements of a specific shape to working surfaces, placing those fixture elements with the possibility of rotation towards the axe that are parallel to the axes of the device, and also the design of the device for anchor knot activation in the shape of spacious cam gear [36].

The given aim is achieved by the presence of a hollow cylindrical case in our device with the left pipe reducer placed at its lower part and the right pipe reducer placed at the upper part of the device. The anchor knot with fixture elements, reversing gear in the shape of planetary gear consisting of master hollow shaft-gear and carrier gear with satellites are also present.

The external working cylindrical surface of fixture elements is obtained by the motion of the generant in part of the Archimedean spiral and enabling fixture elements to rotate around the axes parallel to the axis of the device in order to change the external diameter of the device. It ensures bigger interaction area with internal surface of a casing string, which prevents its contact damages that may be the source of its further destruction. Besides that the offered construction of fixture elements makes it possible to use the designed device in casing strings of different diameters without the replacement of the very fixture elements.

The device for pipes unscrewing contains hollow cylindrical case 1 (fig. 2) that has geared surface 2 on its

https://doi.org/10.1051/e3sconf/202128009002

inner cylindrical surface and with left pipe adapter at its lower part 3.

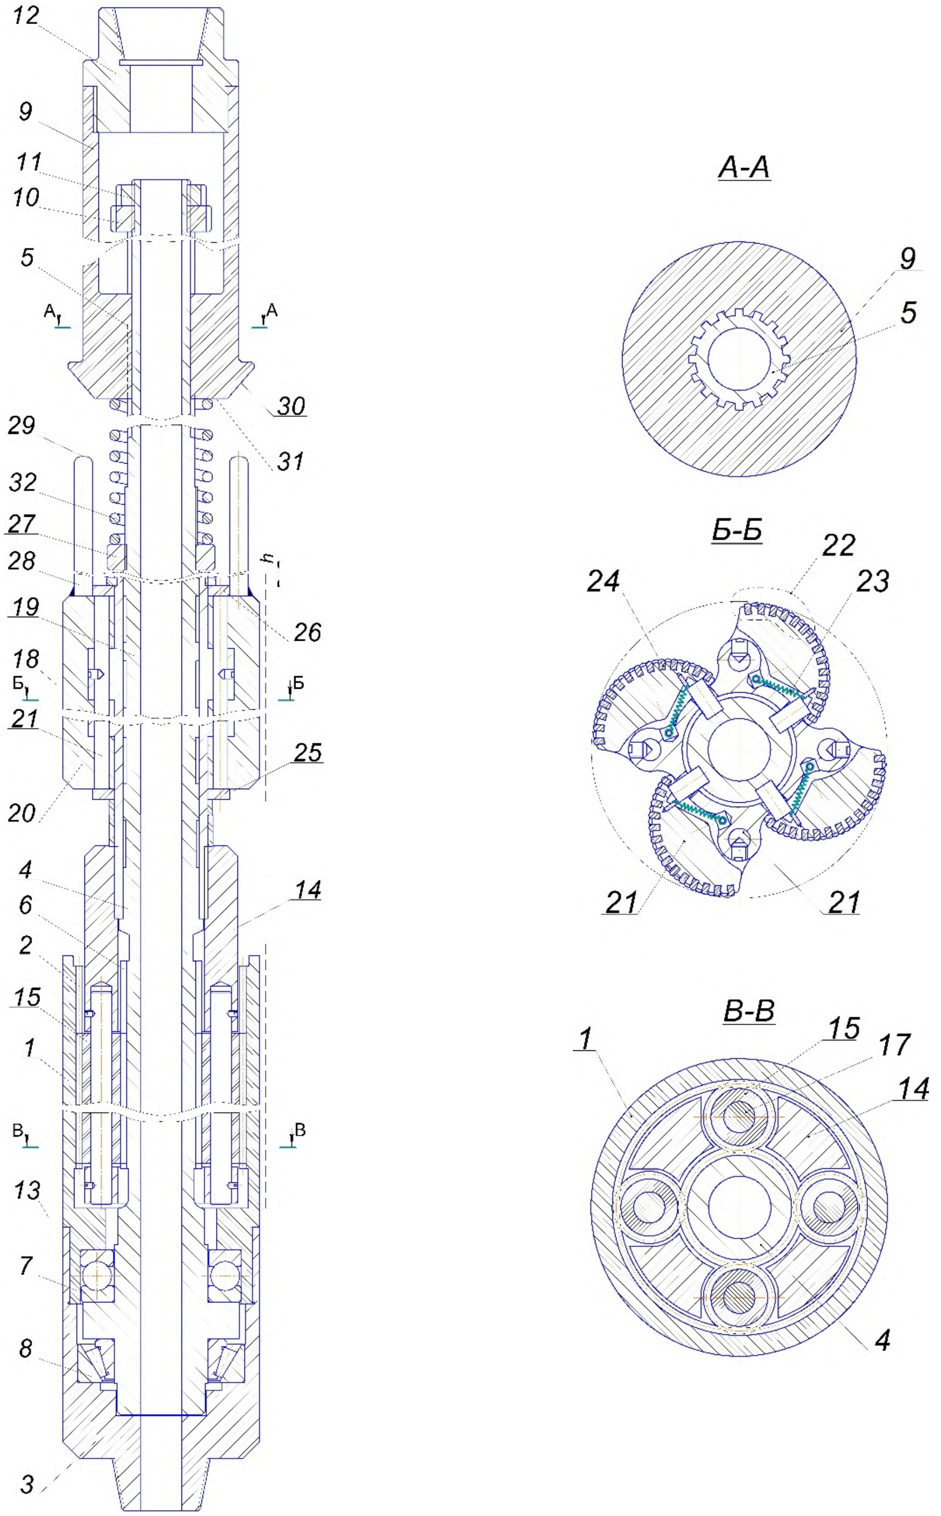

Fig. 2. The scheme of the device for unscrewing the captured column of pipes.

Inside the case 1 the hollow shaft-gear 4 is installed the upper end of which is designed in the shape of splined surface 5, closer to the lower end of shaft-gear 4 there is geared surface 6. The shaft-gear 4 is placed with the ability of rotation towards the case 1 of the device. With this purpose the rolling bearings 7 and 8 are placed at the lower part between them. On the upper part of the shaft-gear 4 on splined surface 5 the spacing sleeve 9 is placed and it is able to perform limited axial movements towards shaft-gear 4. The limitation of this movement is ensured by screw 10, screwed at the geared end of shaft-gear 4 and fixed from unscrewing by locking nut 11. At the upper part of spacing sleeve 9 the right pipe adapter 12 is fixed with the help of screwed joint, adjoining it axis.

The device also has the reversing gear 13 in the shape of planetary gear, consisting of master hollow shaft-gear

 https://doi.org/10.1051/e3sconf/202128009002

4, carrier gear 14 with satellites 15 placed with the possibility of interaction with external geared surface 6 of shaft-gear 4 and internal geared surface 2, designed in the cylindrical hollow case 1 of the device. The satellites 15 are placed at the respectful hollows 16 of the carrier gear 14 on the axes 17.

The offered design of the device for pipes unscrewing also contains anchor knot 18 consisting of cylindrical case 19, immovably (e.g. by screw connection) fixed at the upper part of carrier gear 14 and placed with the possibility of rotation at shaft-gear 4. The anchor knot 18 also has fixture elements 20 (ranging in number from 3 to 12) placed with the possibility of rotation around axes 21, placed in case 19 parallel to shaft-gear 4 axis. The external working cylindrical surface 22 of fixture elements 20 is designed by the motion of the generant in part of the Archimedean spiral. Fixture elements 20 are manufactured from solid material like steel, processed by relevant thermochemical methods (cementing, boration, chromizing, etc.) and thermal (hardening+low dismissal) of treating. The working surface 22 is carved or armed by hard-alloyed insertion pieces 23. The anchor knot 18 also has extension springs 24 (according to the number of fixture elements 20), the force of them being directed at rotation of fixture elements 20 towards O-O axis of the device.

Apart from that the anchor knot 18 is provided by two spacers 25 and 26, placed at case 19 in order to fix axes 17 axially.

The anchor knot 18 is placed at shaft-gear 4 with the possibility of relative rotation and limited axial movement by the magnitude h that can be altered by adjustor nut 27, screwed at screwed surface, performed at shaft-gear 4 under splined surface 5.

The anchor knot drive of the patented device consists of abutting carrier gears 28, immovably fixed at upper end faces of fixture elements 20 and designed in the shape of cylindrical shafts with spheric endings 29. The lower part of spacing sleeve 9 consists of two surfaces: cutaway conus 30 and flat end surface 31. The drive also contains the spring 32, placed between upper flat end surface of adjustor nut 27 and flat end surface 31 of spacing sleeve 9.

The sizes and mutual location of cutaway conus 30 and spheric endings 29 of carrier gears 28 ensure their interaction during the movement of spacing sleeve 9 (along splined surface 5 of shaft-gear 4) in the direction of spring 32 contraction.

Before the device installation it is necessary to conduct well logging that will make it possible to clearly define the place where the device should be installed [29, 30, 37, 38] on the part of the pipe that is not damaged.

The device operates the following way. The offered device (fig. 2, 3) altogether with fishing tools: taper tap, drill pipe spear etc., attached to the lower pipe adapter 3, is lowered altogether with fishing string of right drilling pipes with the help of right upper pipe adapter 12.

Fig. 3. Laboratory experimental model of a device for unscrewing a captured column of pipes.

This process is continued in the cased wellsite up to the lineup of the fishing tool with the upper end of the stuck string stern. Further lowering sets the upper pipe adapter 12 going altogether with spacing sleeve 9 along the splined surface 5 of shaft-gear 4, pressing string 32 by that. Conic surface 30 of spacing sleeve 9 starts interacting with spheric endings 29 of abutting carrier gears 28 resulting in the action of charge away from the O-O axis of the device. As carrier gears 28 are immovably fixed at the upper faceplate of fixture elements 20, the latter ones, resisting extension strings 24, turn around their axes 21 towards case 19 of anchor knot 18, moving to contact external cylindrical surfaces 22 of fixture elements 20 with external wall of casing string.

Mutual axial location between spheric endings 29 of abutting carrier gears 28 and conic surface 30 of spacing sleeve 9 is adjusted by screw 10, screwed at screwed end of shaft-gear 4 and fixed from unscrewing by locking nut 11.

Spacers 25 and 26 are placed at the external cylindrical case surface 19 from the side of fixture elements edges 20 and mitigate axial movement 21. Besides, spacers 25 and 26 do not let abrasive particles get into junction: the case holes 19 – axis 21 – fixture elements holes 20, preventing jamming and device incapacitation.

The anchor knot is fixed in the casing pipe by drilling string weight indicator.

Working surfaces 21 link with casing pipe wall. The reliability of this link is ensured by the design of fixture elements working surface by the motion of the generant in part of the Archimedean spiral and thread cutting fixture elements 20 on working surface 21 or reinforcement those surfaces by hard-alloyed insertion pieces 23. The link of fixture elements 20 with the external surface of casing pipe wall prevents anchor knot 18 from rotation in cased borehole.

The rotation is initiated by drilling string. As the anchor knot does not let carrier gear 14 rotate towards the O-O axis of the device, planetary gear 13 is turned into common spindle reversing gear. Drilling string rotation through upper right pipe adapter 12, spacing sleeve 9, through splined surface 5 drags over to shaft-gear 4 and further through satellites 15, placed in the hollows 16 at axes 17 onto case 1 of the device. The latter, having the possibility of rotation towards shaft-gear 4 at rolling bearings 7 and 8 sets anticlockwise (reverse) rotation of the lower left pipe adapter 3 with the fishing tool.

After fishing tool is screwed into the emergency pipe body the unscrewing of the weakest thread in emergency drilling string is begun.

Axial movements that appear during fishing tool cutting-in and pipes unscrewing is ensured by axial movement (sliding) of satellites 15 along geared surfaces 2 and 6 respectively in case 1 of the device and at shaft-gear 4 at the expense of spacing gap h between upper part of anchor knot 18 and lower edged surface of adjustor nut 27. Depending on fishing tool schedule and unscrewed pipes thread this spacing gap is adjusted by means of according tightening adjustor nut 27.

After the weakest screwed joint assembly is unscrewed which is noted by drilling string weight indicator, the rotation of the fishing string is stopped and it starts being lifted. The impact of spring 32, placed between adjustor nut 27 and flat end surface 31 of spacing sleeve 9, sets the spacing sleeve 9 going towards shaft-gear 4. Alongside with that as a result of upward axial movement of conic surface 30, the thrust force on spheric endings 29 of carrier gears 28 is reduced – fixture elements 20 under the impact of springs 24 reset, unlocking the device from casing string. The device with the unscrewed pipe or several pipes is lifted from the wellbore.

4 Conclusions

1. It is often the case with oil and gas production industry when emergency situations associated with catching (wedging up) drilling string or pumping-compressor pipes. And the number of these occasion call for the pipes unscrewing from the caught pipe.

2. The most popular way of unscrewing pipes from the caught pipe is the use of pipes with anticlockwise screw. This way is labor-consuming, power-consuming and causes environmental pollution.

3. The use of the way mentioned in clause 2 of the conclusion causes extra pollution to the environment by transportation means delivering and taking away big amounts of tools with anticlockwise screw and sustainable operation of drilling rig engines when the available pipes with clockwise screw are replaced by the ones with anticlockwise screw, and when the operation is completed, the reverse replacement takes place. The total length of pipes with anticlockwise screw is equal to the length of the wellbore and may comprise from 1000 m up to 6000 m and more.

4. The offered construction of the device that functions as a transformer of rotation direction is lowered into the wellbore with the aid of existing pipes with clockwise screw after which there is no necessity to use pipes with anticlockwise screw. It reduces the time of preparatory works needed to remove the emergency and respectively the environmental impact is shortened.

5. The cost of the offered device is next lower order than with the use of pipes with anticlockwise screw.

6. In addition, in order to prevent environmentally hazardous situations oil and gas production sites should employ highly qualified and certified staff. This approach will reduce the impact of human factor as the reason of emergency situations by forming adequate response skills during emergencies when wellbores are being constructed. [39, 40, 41]. Specialists should be trained with the use of modern educational technologies that will make it possible to imitate real life conditions and get practical experience of proper response to incidents in the workplace [42].

[1]Institute of telecommunications and global information space of NAS of Ukraine, Kyiv, Ukraine
[2]Taras Shevchenko National University of Kyiv, Kyiv, Ukraine

Abstract. Determining the quantitative degree of connection between logging error and the corresponding error of oil and gas wells electrometry inverse problem solving is considered. A quantitative method to determine the magnitude of the error of solving the inverse problem depending on the magnitude of the logging error for a given model of a single layer or section as a whole is described. Examples of determining the error of the inverse problem for real well materials, taking into account the actual measurement error, are given. A method for determining the characteristics of the spatial resolution of electrometry methods is described. Examples of its use for low-frequency induction logging equipment are given. The proposed methods allow to determine the areas of equivalent solutions and the areas of existence of stable / unstable solutions of the inverse electrometry problem.

1 Introduction

The geoelectric parameters definition problem of the section helps to answer two questions [1]:

- Where is the useful fluid?
- How many are there?

Determining these geoelectric parameters requires solving an inverse mathematical problem that links the data of direct measurement of some apparent conductivity (AC) or apparent resistivity (AR) values around the well space with unknown values of these parameters of the model of the studied section. The main method of solving such problems is numerical. But almost any numerical solution involves error. So the final result of solving such a problem will not be a numeric value (or a vector in vector space), but some area of possible values. However, all elements in this area will have the same opportunity to be the solution of the problem. This means that they are equivalent. The size of the area of equivalent solutions that accord the same initial conditions determines the spatial resolution of the solution. In general, it allows us to identify areas of sustainable solutions. And accordingly, identify areas where there are no stable solutions.

2 Analysis of previous publications

There are many reasons for the problem of defining the boundaries of productive intervals in vertical and inclined vertical oil and gas wells. One of the main reasons is the insufficient (for many of the conditions inherent in the Dnipro-Donetsk depth) vertical resolution of geophysical well research (GWR) complexes used in practice. The use unfocused laterolog tools (BKZ), where most sondes are not symmetrical is one of the factors of such a problem. To illustrate it we can cite the well-known problem of determining the position of water-oil contact, the solution of which is devoted to many studies.

The error in determining the boundaries of productive intervals leads to an error in determining the daily flow rate of useful fluid (due to inaccurate determination of perforation) and, accordingly, is a factor in the error of the initial conditions of further technical operation of the well as an anthropogenic loading on the environment.

The work is part of a study of the possibilities of improving the efficiency of solving inverse problems of well electrometry [2-4].

In general, many program-methodological and analytical methods have been developed to analyze the impact of violation of technical requirements for the exploitation of wells on the ecosystems of hydrocarbon production areas [5-13].

The problem of the impact of the oil and gas wells exploitations on the ecological state of the geosphere is more than topical [14-17].

Applied tasks even include the study of the effects of hydrocarbon extraction on the development of regional tourism. This is more than relevant because the Carpathian region is potentially oil and gas and is one of the centers of tourism in Ukraine [18-23].

The environmental impact of oil and gas well operation is also similar to the environmental impact of fuel combustion in boilers [24-27].

In addition, the inevitable use of radioactive methods together with electrometric methods in GWR requires solving the problem of the impact of such methods on different components of the geosphere [28-31].

* Corresponding author: myrontsov@ukr.net

The combination of all these approaches makes it possible to use already developed decision support systems [32-40].

It should also be noted that to increase the efficiency of numerical calculation in recent decades has become widely used method of physical simplification. This method is widely used in solving modeling problems of engineering problems and is to simplify the equations of mathematical physics by introducing simplifications that take into account the physical content of processes [41-51].

3 The solution error of the inverse problem and the spatial resolution of the inverse problem

3.1 Error solving the inverse problem

The main error that occurs in the problems of electrometry is a significant measurement error (sometimes the allowable error is an error of 20-40%).

In addition, there may be other possibilities of error. The occurrence of an error in solving the inverse problem can be due, for example, to the following reasons:

1) its mathematical description is inaccurate, in particular inadequately or inaccurately described the model itself or its parameters, etc .;

2) the used method of solving is not accurate;

3) arithmetic operations and outputting data is rounded.

Errors that correspond these reasons are called:

1) irreversible error;

2) the error of the method;

3) computational error.

For the future, the main thing will not be the nature of the error and the fact of its existence. From this point of view, we will investigate the relationship between the magnitude of the error in the initial conditions and the magnitude of the error in solving the inverse problem and consider a method for studying the areas of equivalent solutions.

3.2 Three-layer model

As a geoelectric model of the medium we will consider a three-layer model (Fig. 1).

This model consists of a well (specific resistivity (SR) of mud – ρ_W), invaded zone (or «zone»; SR of zone – ρ_Z) and uninvaded zone (or «layer»; SR of layer – ρ_B).

This model is simplified, but adequately describes the most relevant reservoirs inherent in the conditions of the Dnipro-Donetsk depth (including complex, thin-layer and anisotropic reservoirs, residual oil saturation collectors, abnormally low resistance reservoirs, faulty collectors, etc.).

To determine the values of the reservoir parameters, we consider the following depending on the type of fluid saturation (Table 1).

For simplicity, we will assume from the beginning that the layer has infinite thickness. The case of studying layers of finite thickness requires consideration of the so-called boundary effects [2-3].

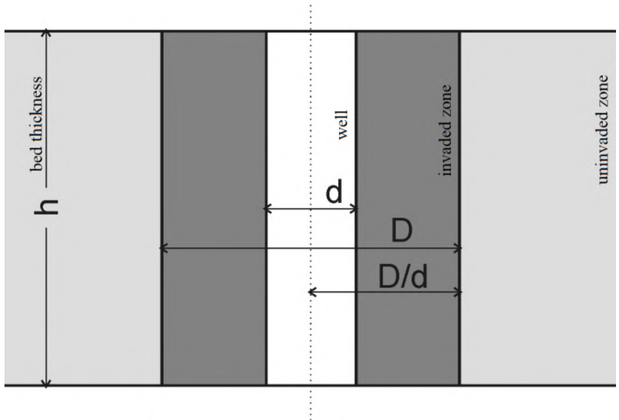

Fig. 1. Three-layer formation model

Table 1. Typical parameters of the layers.

Saturation type	ρ_B, Ohm·m	ρ_Z, Ohm·m	D/d
water-saturated	4,5	20	5
oil-saturated	8,5	30	4
gas-saturated	50	30	5

3.3 Array induction tool

Our geoelectric model is described by several unknown parameters (for the three-layer infinite model – three). To find them, we need to have at least three known values of measured conductivity or resistance in front of each layer.

Existing and widely used induction logging equipment in the world provides such an opportunity. Such equipment consists of four (seven) probes of low-frequency induction logging (IL) – 4IK (7IK). The lengths of the sondes are 0.5, 0.85, 1.26, 2.05 meters (for the 7IK three more sondes of lengths 0.15, 0.25, 0.35 meters are added).

The given methods of research of connection of data of direct measurement with unknown values of parameters of model of the investigated layers are applied without restriction of generality and for other multiprobe systems of electrometry. Such equipment consists of BKZ, lateral logging tool (BK) and low-frequency induction logging tool (AIK) and gives us for each layer (measuring point) even 9 measured values that are not linearly dependent. These are six values measured by the BKZ complex, one value measured by the BK, two values (active and reactive) measured by the AIK.

4 Solution of the inverse problem in the presence of an error

4.1 The magnitude of the equipment error

The simplest way that can be chosen to study the effect of error in the boundary conditions of the inverse problem on its final result is to find the range of possible solutions that correspond to the range of possible values of the boundary conditions. That is the purpose of the study will not be the cause of the error, but how its magnitude affects the error magnitude of solving the inverse problem.

Before that, let us recall two definitions. A correctly posed (well-difined) problem is a problem that satisfies the following three requirements:

– the problem has a solution (requirement of existence);

– the existing solution is unique (requirement of unity);

– the existing and unique solution continuously depends on the input data (continuity condition).

Unstable problem is a problem for which a small error in the initial data can lead to a much larger error in the solution.

Let us now investigate the mapping of the range of admissible values of each measurement vector into the space of the vectors of the geoelectric section model, using the values of the errors that correspond to what is really possible.

One of the possible ways to determine the magnitude of the error is:

– for BKZ (not more than) in % ($\tilde{\rho}$– AR):

$$\varepsilon_{BKZ} = \pm\left(2{,}5 + 0{,}004\left(\frac{5000}{\tilde{\rho}} - 1\right)\right);$$

– for IL (not more than) in mSm/m ($\tilde{\sigma}$ – AC):

$$\varepsilon_{IL} = 0{,}03\tilde{\sigma} \pm 1;$$

– for BK (not more than) 5%.

4.2 Algorithm for establishing areas of equivalent solutions

We will demonstrate "the simplest way" on an example of logging by a 4IK complex in two wells.

The error will be set in two ways:

– the measurement of each probe has an error within a given interval, i.e. is not a number but a confidence interval:

$$\left(1 - \frac{\varepsilon}{100}\right)\tilde{\rho} < \tilde{\rho} < \left(1 + \frac{\varepsilon}{100}\right)\tilde{\rho};$$

– the resistance of the mud is determined with some error, i.e. ρ_W can take any value from the range:

$$(1-\delta)\rho_W < \rho_W < (1+\delta)\rho_W.$$

The second type was chosen to study the stability of the solution from well parameters. Consider the solution of the inverse problem for the already mentioned wells: Vatynska (Fig. 2) and Eganska (Fig. 3).

The error values were set as follows: ε = 10% (Fig. 2.a, 3.a), ε = 20% (Fig. 2.b, 3.b).

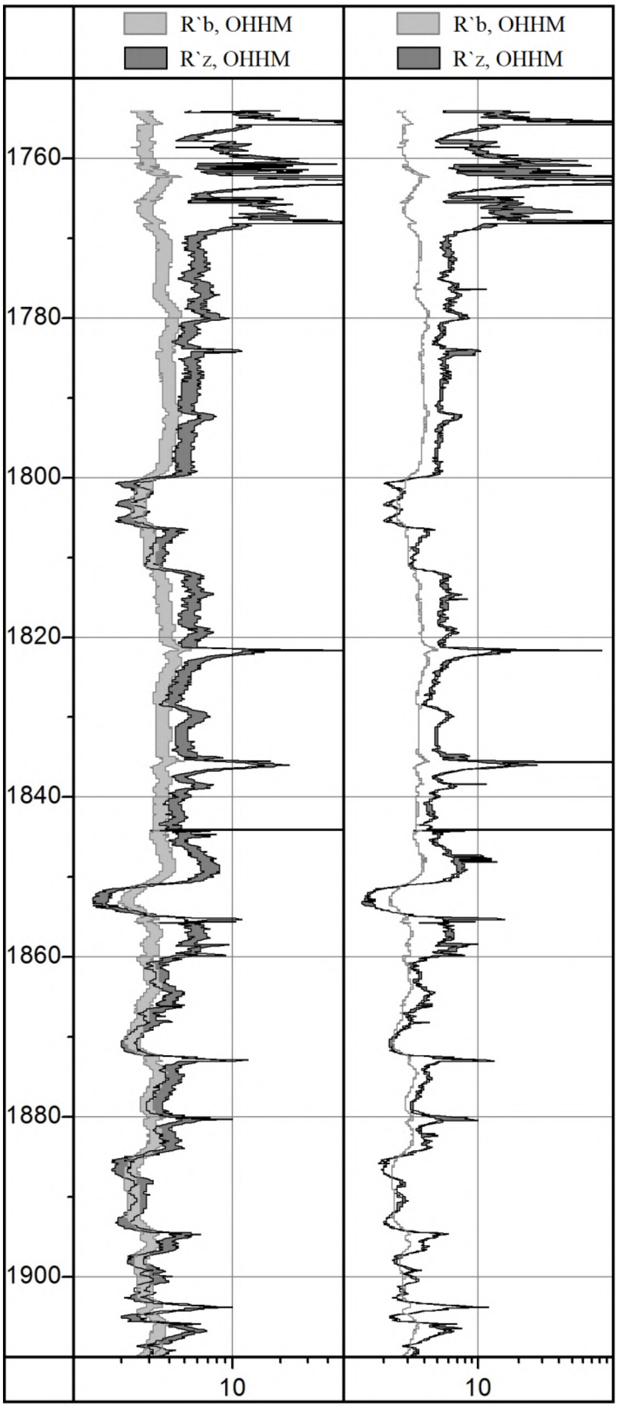
4.3 The inverse problem solving method without error in the initial conditions

The effectiveness of the inverse problem solving method is determined:

– by the choice of method for determining the measurement data of the sondes for the selected parameters of the environment;

– by choosing the parameter "proximity" of the calculated probe readings and real;

– by the method of selecting model parameters for the selected parameter "proximity".



a b

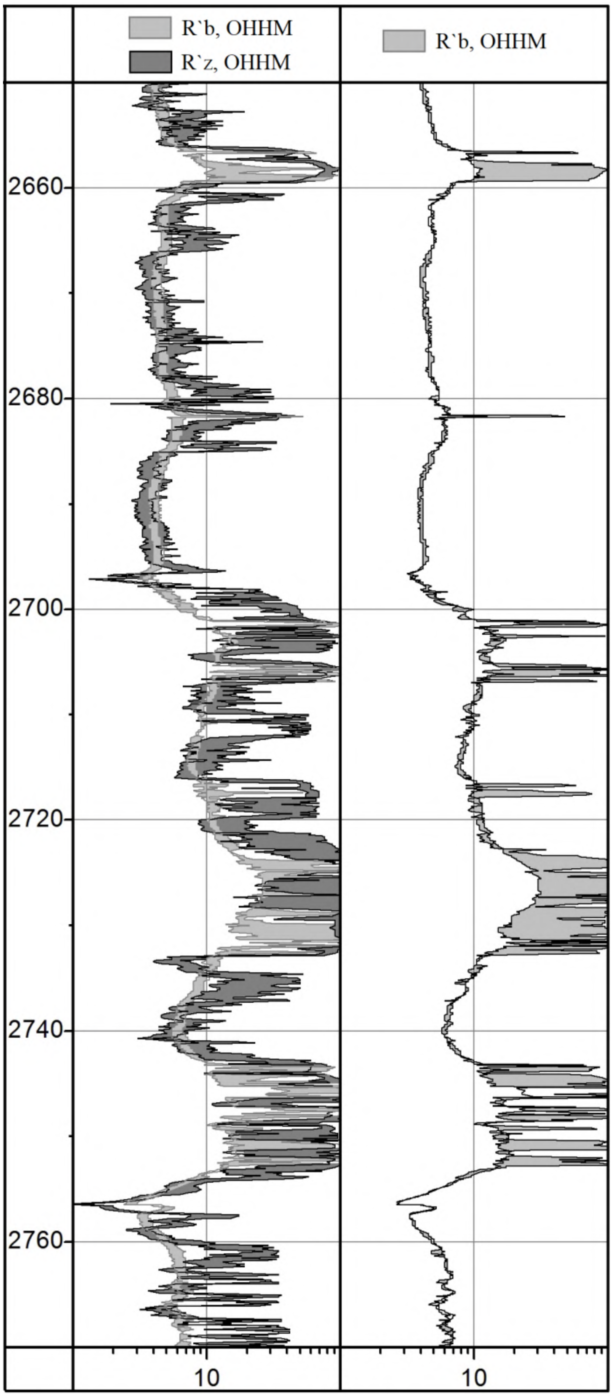
Fig. 2. Well «Vatynska» (ρ_W=1.6 Ohm · m). The result of solving the inverse problem

These questions can be paraphrased accordingly as:

– choice of the method of solving the direct problem (finite differences, finite elements, integral currents, semi-analytical solution, etc.);

– the type of functional that will be minimized when solving the inverse problem (previously this item looked like "choosing the visually closest palette");

– method of iterative process of solving the inverse problem.



a b

Fig. 3. Well «Eganska» (ρ_W= 0.34 Ohm · m). The result of solving the inverse problem

We will not consider the first and third issues, assuming that they are resolved.

As a criterion for the proximity of the found solution with the desired true value, we can consider the minimization of the functional:

$$F(\rho_1^T, \dots, \rho_n^T) = \frac{1}{n}\sqrt{\sum_{i=1}^{n}\left(\frac{\rho_i^T - \rho_i^P}{\rho_i^T}\right)^2},$$

where is n – the number of equipment sondes; ρ_i^T– calculated values of AR for the model under consideration; ρ_i^P – actually obtained values of AR.

There are also some variations of the functional record, which will be minimized in the process of solving the inverse problem. For example, in the form:

$$F(\rho_1^T, \dots, \rho_n^T) = \frac{1}{n}\sqrt{\sum_{i=1}^{n}\left(\frac{\rho_i^T - \rho_i^P}{\delta_i \rho_i^T}\right)^2},$$

where δ_i – the relative error of the i probe.

Or:

$$F(\rho_1^T, \dots, \rho_n^T) = \frac{1}{n}\sqrt{\sum_{i=1}^{n}\left(\frac{\rho_i^T - \rho_i^P}{\delta_i \rho_i^T + \chi_i}\right)^2}, \qquad (1)$$

where χ_i – the absolute error of the i probe.

We will consider the functionality of the form:

$$F(\rho_1^T, \dots, \rho_n^T) = \sqrt{\sum_{i=1}^{n} K_i\left(\frac{\rho_i^T - \rho_i^P}{\rho_i^T}\right)^2}, \qquad (2)$$

where K_i – weight coefficients of each sonde of the complex, which can be changed by the interpreter.

Several studies have been devoted to the choice of different values of weights.

It is clear that the change in weights will significantly affect the size of the area of equivalent solutions, because it can reduce the impact of sondes that have a larger measurement error and increase the impact of sondes that have a smaller measurement error, for example.

Further research will be devoted to this issue. In this study, without loss of generality, we will assume that:

$$\forall i: K_i = 1. \qquad (3)$$

4.4 Examples of the inverse problem solving taking into account the error in the initial conditions

To demonstrate the method, we take the real well material and assume that the result is obtained with an error (Fig. 2.a, Fig.3.a – ε = 20%; Fig. 2.b, Fig. 3.b – δ = 0.2). For such values of possible initial intervals we will solve the inverse problem (we will define ρ_B,ρ_Z that are designated as R`b, R`z in Fig. 2,3).

Note that in Fig. 3.b shows the results only for the AR of layer, because the intervals of possible values of the zone are frankly chaotic and do not carry any information, resembling a random number generator and therefore not given. This chaotic nature is evidence of a typical example of an unstable solution, when for each specific value of the measurement data we have a specific solution value, but a small change in the measurement data corresponds to a large (orders of magnitude larger) change in the solution value of the inverse problem. This is also an example the way of how a solution can satisfy a condition of continuity but not be stable.

Based on the results obtained, the following conclusions were made.

For a well filled with clay drilling mud (Fig. 2):

– the inverse problem of the 4IL complex within the values of the model parameters is stable relatively to the measurement error (the range of possible values of the model parameters is almost proportional to the range of possible measurement values (Fig. 2.a));

– the inverse problem for the 4IL complex within the values of the model parameters up to 10 mSm/m is stable relatively to the change of ρ_W (the range of possible values of model parameters is almost proportional to the range of possible drilling fluid values (Fig. 2.b));

– the inverse problem for the 4IL complex within the values the model parameters more than 10 mSm/m satisfies the condition of continuity, but is not relatively to the change of ρ_W (the range of possible values of model parameters is much larger than the range of possible ρ_W values (Fig. 2.b));

– values of R`z are more "sensitive" to change of parameters of a well, than values of R`b.

For a well filled with saline drilling mud (Fig. 3):

– the inverse problem of the 4IL complex within the values of the model parameters up to 10 mSm/m is stable relatively to the measurement error (the range of possible values of the model parameters is almost proportional to range of possible measurement values (Fig. 3.a));

– the inverse problem of the 4IL complex within the values of model parameters more than 10 mSm/m satisfies the condition of continuity, but is not stable relatively to measurement error (the range of possible values of model parameters is much larger than the range of possible values of measurements (Fig. 3.a);

– the inverse problem of the 4IL complex is not stable relatively to the change of ρ_W (the range of possible values of one of the parameters of the model (namely R`z) is much larger than the interval of possible values of ρ_W;

– the parameter R`b has both a stable region of definition (up to 10 mSm/m) and an unstable region of definition (more than 10 mSm/m), as can be seen in Fig. 3.b.

There are many similar examples of wells and complexes, but the main one is the fact that, in principle, there are areas of unstable solutions in wells.

That is, by setting specific values of the AR, we will, of course, get a specific value of the solution, but it may be unstable. It is clear that such a solution cannot be used while GWR.

Alternatively, in further interpretation, it will lead to erroneous conclusions regarding the determination of well performance characteristics.

So, we come to the conclusion that it is not enough to have a way to solve the inverse problem on its own. We also need to have a method that will allow to determine the areas of stability of the solutions of the inverse problem for each section model and each electrometry complex.

5 Spatial resolution characteristics of solving the inverse problem

Consider the space of the parameters $\mathbf{P}$ of the studied objects $\mathbf{p}$ and the space $\mathbf{G}$ of possible values $\mathbf{g}$ of measurement by the well-logging complex. In order for the problem to have a solution, we will require that the number of independent measurements be greater or equal to the number of required parameters of the model. There is a unique mapping: $\mathbf{P} \rightarrow \mathbf{G}$ (we will denote the corresponding mapping function G). Consider the features of the inverse mapping (we will denote the corresponding function G^{-1}), which in the case of mapping one element will be considered unambiguous. If the mapping object is not one element $\mathbf{g}$, but an area $\mathbf{g} + \Delta\mathbf{g}$ where $\Delta\mathbf{g}$ takes any values within the allowable error, then the image of such a mapping will also be some. Consider the following mapping:

$$\mathbf{p} + \Delta\mathbf{p} = G^{-1}(\mathbf{g} + \Delta\mathbf{g}). \quad (4)$$

Note that since the inverse problem is nonlinear, the value depends on both the model itself and the measurement error: $\Delta\mathbf{p} = \Delta\mathbf{p}(\mathbf{p}, \Delta\mathbf{g})$. The measurement error also generally depends on the model of the environment: $\Delta\mathbf{g} = \Delta\mathbf{g}(\mathbf{p})$.

Such a complex dependence does not allow to introduce a general simple concept and definition of the spatial resolution of the equipment not only for the whole range of parameters of all possible current models of sections, but even for a set of several separate models and requires the study of quantitative dependence (4) for each model.

Accordingly, we can talk about the characteristics of the spatial resolution of specific equipment only for a specific model of the section: even with a slight change in the parameters of the model, the characteristics can change significantly. This is exactly what we observed in the previous section.

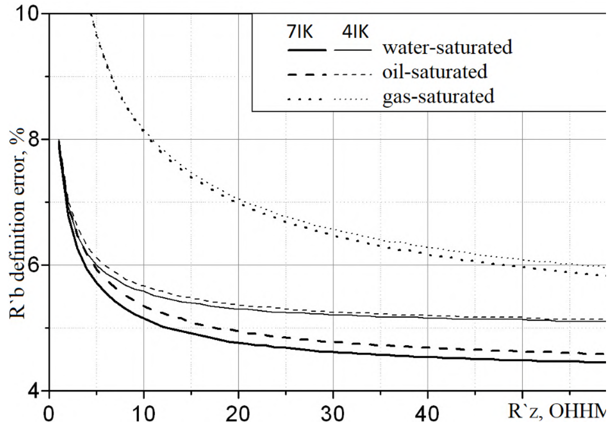


Fig. 4. Dependence of the error in determining the ρ_B on the ρ_Z

Therefore, the analysis of such characteristics should be performed for a separately selected model.

For each such selected model we will perform the following steps:

1. Set its parameters – determine the vector of model parameters $\mathbf{p}$ (we will use table 1).

2. Solve a direct problem for $\mathbf{p}$ – determining the vector of measurements $\mathbf{g} = G(\mathbf{p})$.

3. Solve the inverse problem for a definite $\mathbf{g}$ – finding an element such that:

$$\mathbf{p}` = G^{-1}(\mathbf{g}) = G^{-1}(G(\mathbf{p})).$$

4. Compare $\mathbf{p}`$ and $\mathbf{p}$ – determine the accuracy of solving the inverse problem.

If it does $\mathbf{p}`$ not differ from $\mathbf{p}$ (within the allowable, arbitrarily small, predetermined error), we will assume that:

$$\mathbf{p}` \equiv \mathbf{p}. \tag{5}$$

Execution (5) will mean that the obtained characteristic of the spatial resolution is correct and does not depend on the method of solving the inverse problem.

5. Solving the inverse problem for the area $\mathbf{g} + \Delta\mathbf{g}$ – finding the set of possible models $\mathbf{p}+\Delta\mathbf{p}$ that correspond $\mathbf{g} + \Delta\mathbf{g}$ (determination of the error $\Delta\mathbf{p}$ depending on the given value of the error $\Delta\mathbf{g}$).

6 Results

We will demonstrate this connection between the registration error and the error of possible determination of the required parameters.

The error will be set separately for each sonde. To qualitatively explain the expected results, it is enough to use the approximate Doll`s theory and record the AC measured by each sonde, ignoring the signal from the well in the form:

$$\sigma^i = \frac{g_Z^i}{\rho_Z} + \frac{g_B^i}{\rho_B}, \tag{6}$$

where σ^i – the apparent conductivity of the ith probe; g_Z^i, g_B^i – geometric factors of the invaded zone and the layer.

It is obvious that the relative accuracy of determining the SR of the layer and the invaded zone is
related to the relationship between the first and second terms in (6).

Yes, when:

$$\frac{g_Z^i}{\rho_Z} << \frac{g_B^i}{\rho_B}, \tag{7}$$

the parameters of the invaded zone are determined with a much larger error at than the parameters of the layer at $\rho_Z = const$.

In addition, condition (7) is fulfilled particularly strictly with increasing penetration, when, in addition, condition (6) is amplified even more. The error in determining the parameters of the near zone is improving with decreasing penetration, because the condition significantly weakens condition (7). But, among other things, this is confirmed by direct numerical simulation of the spatial resolution characteristics.

Thus, Fig. 4 shows the dependence of the accuracy of determining the SR of the layer from the SR of the zone, Fig. 5 – the dependence of the accuracy of determining the SR of the layer on the diameter of the zone, Fig. 6 – the dependence of the accuracy of determining the SR of the zone on the diameter of the last one.

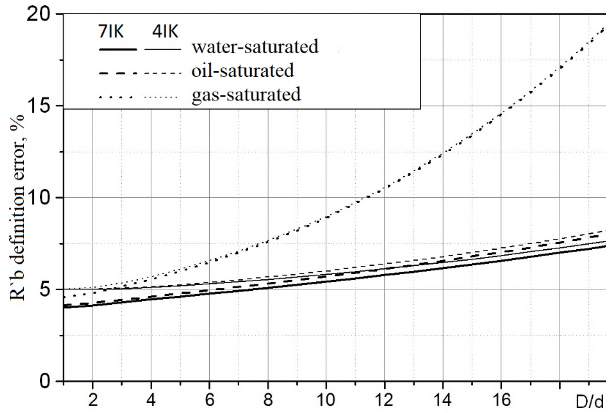

Fig. 5. Dependence of the error in determining the ρ_Z on the diameter of the zone

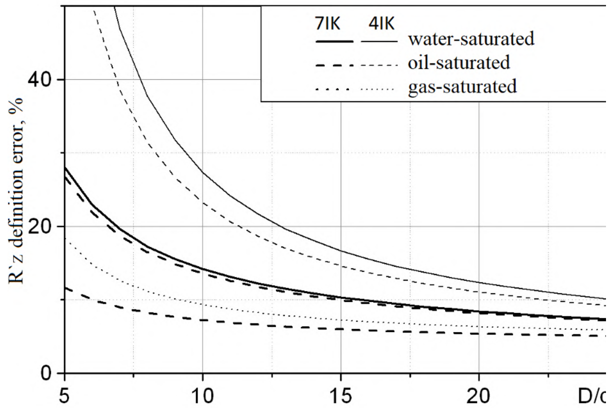

Fig. 6. Dependence of the error in determining the ρ_Z on the diameter of the zone

7 Conclusions

These results lead to the following conclusions:

– Before the practical application of any method of solving the inverse problem, it is advisable to explore the areas of stability of its solutions, which will allow them to be used in the future without losing useful information.

– In order to be able to effectively further work with the obtained results, it is also advisable to explore the areas of equivalent models that correspond to the real error of logging and its geophysical conditions.

– The given method of research of spatial resolution of the solution of the inverse problem of electrometry of oil and gas wells allows to investigate effectively areas of stability of its decisions and areas of equivalent models corresponding to a real error of logging and its geophysical conditions.

The question of why use (2) is more adequate than use (1) will be covered later.

Abstract. A comparative analysis of the ecological (environmental) educational component of the training in students of Natural Science Departments (Chemistry, Biology, Earth Sciences, Ecology) and future teachers of natural sciences has been carried out. The general and professional competences, program results of training, and applicants training educational programs on the example of several Ukrainian universities are analyzed. It is revealed that the formation of environmental competence is carried out by acquiring environmental education by means of interactive technologies, forms, and methods of organizing the educational process. The positive influence of students' involvement in research, environmental, ecological, and naturalistic work in extracurricular time on the formation of their environmental competence has been confirmed. The role of educational and industrial practices in the process of students' professional training and the formation of their environmental competence is emphasized.

1 Introduction

The strategy of the state ecological policy of Ukraine for the period till 2030 provides the following: introduction of the ecosystem approach in branch policy; integrated environmental management and implementation of international standards; taking into account the environmental component during economic activity; implementation of international environmental initiatives in Ukraine [2].

The document emphasizes the importance of maintaining air quality, reducing greenhouse gas emissions; protecting natural waters, forests, lands and soils; developing a national biosafety system; preserving the biological and landscape diversity, etc.

Ukraine has developed a national system of continuous sustainable development goals, which should become the foundation for overcoming imbalances in the economic, social, educational and environmental spheres; thus, it will contribute to the quality of life of present and future generations in harmony with the environment, as well as it will guarantee socio-economic and environmental stability, including a decent level of education and public health.

An important task today is the formation of ecological competence, environmental culture and environmental worldview of all segments of the population. In our opinion, the issue of formation of ecological competence of specialists of water quality analysis, forestry, agriculture, mining industry is especially urgent; nevertheless, specialists in Chemistry, Biology, Geography, Ecology; as well as teachers of natural sciences should also be covered, for the state of the environment will largely depend on the level of their ecological competence.

2 Literature review

The Second United Nations Conference on the Environment (Rio de Janeiro, 1992) declared the Agenda for the XXI Century program document, which for the first time set out the basic provisions for sustainable development. This is a kind of model of socio-economic development, in which the vital needs of the current generation are met in such a way that future generations are not affected by the depletion of natural resources and environmental degradation [3].

"Environment for Europe" congress took place in Kyiv in 2003, during which the member states of the United Nations Economic Commission for Europe (UNECE) have adopted the "Declaration on Education for Sustainable Development". It declared that education is one of the tools that ensure environmental protection and sustainable development of society. The world community has begun to talk more and more about the role of education in the transition of humanity to the principles of sustainable development. The UNECE Ministers of the Environment invited countries to include the concept of sustainable development in education

* Corresponding author: melnychenko.ruslana@gmail.com

systems at all levels (preschool, secondary, higher); as well as in non-formal and out-of-school (extracurricular) education.

At the Eighth Conference of EEC Ministers of the Environment "Environment for Europe" (Batumi, 2016) it was stated that by 2030 it is necessary to achieve that all students acquire the knowledge and skills necessary for sustainable development, which will substantially enhance the relevant competence [4].

In general, in the European educational space, competence is defined as a dynamic combination of knowledge, skills, abilities, ways of thinking, personal qualities, attitudes and values, which determines a person's ability to successfully carry out professional and / or educational activities. Competences underlie the qualifications of graduates of higher education institutions (HEIs) [7; 28].

European researchers attach great importance to environmental competence. For example, Roczen proposed environmental competence model, which includes cognitive and motivational components. Thus, author examined the structure between different forms of environmental knowledge as well as connection with nature and ecological behavior [15]. Researcher identified the connection between human beings and nature as the motivational source of an individual's ecological behavior. This model conceptualizes environmental competence as the interlayer between connection with nature and ecological behavior promoting environmental knowledge. Therefore, the motivational source for ecological behavior is the connection with nature [15; 16].

Frick and colleagues (2004) consider cognitive component the most important one. They distinguish three forms of environmental knowledge: 1) knowledge as a system (knowledge about nature and about environmental problems), 2) action-related knowledge (knowledge about ecological behaviors), and 3) knowledge about corresponding behavioral effectiveness [5]. Scientist claims that ecological behavior is induced by intellectual abilities [26]. However, whereas motivational dispositions strongly impact on ecological behavior [15; 16].

According to Kumar and Rani, environmental education of teachers has a great importance [8], for it is an interdisciplinary subject. It can solve multiple environmental problems, which are faced by the humanity nowadays (global warming, pollution, greenhouse effect, ozone depletion etc.). The research results revealed that out of 600 trainees, 26.00% of teachers showed low level of environmental competencies; 45.33% of applicants possessed moderate level of corresponding competencies. Since teachers play key role in the environmental education, he/she is expected to possess substantial environmental knowledge, environmental awareness, positive environmental attitude and environmental competencies in order to achieve the objectives of environmental education. Therefore, teacher training institutions should take the accountability to organize orientation programs, refresher courses, seminars and workshops on environmental problems and their solution, conferences, which imply great increase in the teachers' qualification [8].

According to Ponomarenko et al., the work on students' environmental competence formation consists of three main stages: 1) environmental orientation formation; 2) environmental professional competence formation (duty, ability, and willingness to make practical decisions following environmental safety); 3) environmental responsibility formation (integral value that allows a person to live in harmony with nature, other people and himself) [12].

The concept of ecological competence of students is the subject of scientific research of many Ukrainian scientists. The issue of formation of ecological competence of university students of biological specialties was researched by Tytarenko [29]. Theoretical and practical issues of environmental training of college students, technical schools are revealed in the works of Hurenkova et al [9], Ridei [14], Rudyshyn [13], who devoted their works to analyzing and solving various issues of professional training of ecologists. The ecological competence of the future biology teacher is the subject of research of Melnychenko [10; 11], Homlya [6], Tsurul [27], [19] etc.

Most authors agree that ecological competence is a category related to environmental awareness, environmental education and culture, corresponding values and thinking. It is formed at the social and household level in different segments of the population and is a *key competence* of graduates of general secondary, specialized secondary, vocational and higher education.

Specialists in the sphere of ecological education and upbringing Pustovit et al. define the «*ecological competence*» as:

– the ability of the individual to make decisions and act with the least harm to the environment;

– ability to responsibly solve life situations, to subordinate the satisfaction of their needs to the principles of sustainable development;

– ability to apply environmental knowledge and experience in professional and life situations, guided by the priority of environmental values and non-pragmatic motivation to interact with the environment;

– awareness of personal involvement in environmental problems solution and responsibility for the environmental consequences of their own professional and domestic activities [13, p. 8].

For students of Natural Science Departments and some technical, engineering and economic specialties, ecological competence is an integral part of *professional competence.*

In particular, Tytarenko considers the environmental competence of biology students as "the ability to apply environmental knowledge and experience in professional and real-life situations, guided by the priority of environmental values, namely: awareness of personal involvement in environmental issues, responsibility for environmental consequences of their professional and home activities." [29].

Shapran claims that the ecological competence of a future biology teacher is a component of professional competence. Its level is manifested through professional and domestic activities, when the acquired environmental knowledge, skills, values, experience are actualized in the ability to make decisions and perform adequate actions, aware of their consequences for the environment [19].

Lukianova and Hurenkova also consider the environmental competence of college graduates as a component of their professional competence; an integral characteristic of business and personal qualities, which seems to "reflect" the level of knowledge, skills, experience necessary for professional activity, as well as the social and moral position of an individual [9].

I. Barna et al. emphasize that during the training of 101 specialty "Ecology" bachelors each student will be able to become a professional, expert in ecology, provided mastery of special and general competencies specified in the standard, including: the ability to assess the impact of man-made factors on the environment; to identify the environmental risks; to use of ICT(s) for environmental research; to inform the public about the state of environmental safety, etc. [1].

Karpenko et al. notes that the formation of ecology competence of future environmental specialists is aimed at the conscious use of acquired knowledge in practice; formation of a system of values, human attitude to the environment. The same authors accordingly link the ecological competence of students with several aspects: 1) the formation of a system of knowledge about the environment; 2) gaining practical experience in using knowledge to solve environmental problems at the local and regional levels; c) forecasting appropriate behavior, activities in the professional sphere and life; d) the need to communicate with nature, the desire to take a personal part in its restoration and preservation [7, p. 10].

A similar opinion concerning the ecological-evolutionary worldview of an individual as a system of principles, views, knowledge, values, beliefs, practical actions that determine the understanding of the unity of social and natural environment is expressed by L. Rybalko, O. Topuzov, L. Velychko. The authors believe that the abovementioned worldview has three important components: intellectual (ecological and scientific-natural knowledge, competencies), emotional-value (caring for the environment, admiration for the beauty of nature), and activity (environmental, research, ecological-naturalistic work) [18, p. 3].

Summarizing the different scientific views and personal experience of training students of students of Natural Science Departments, we note that the formation of environmental competence is carried out during:

− realization of *ecological education* (ecologization of the content of professional disciplines, conducting environmentally friendly training and corresponding types of practice);

− organization of *extracurricular eco-directed work* (nature protection, naturalistic, research activity);

− use of *interactive technologies*, *innovative methods and forms of organization of the educational process* (trainings, projects, case studies, group work, information and communication technologies (ICTs), eco-oriented scientific selectives, etc.).

The aim of our article is to analyze the mechanisms of formation of ecological competence of bachelors of Natural Science Departments, including future chemists, biologists, ecologists, as well as teachers of natural science in the educational environment of the university.

2 Materials and methods

The material for the article was the curricula and educational programs for the training of specialists of the first (bachelor) level of higher education of three universities of Ukraine – Zhytomyr Ivan Franko State University, National Pedagogical Dragomanov University and Kherson State University. The following educational and professional bachelor programs were analyzed: specialty 091 "Biology", 101 "Ecology", 102 "Chemistry", 103 "Earth Sciences", 014.05 "Secondary education (Biology and Human Health)", 014.06 "Secondary education (Chemistry)", 014.07 "Secondary education (Geography)". Thus, the investigation was conducted from the point of view of the ecological (environmental) component of compulsory and variable educational components. Based on the analysis of the Standards of Higher Education, the program learning outcomes and competencies of the relevant specialties of various fields of knowledge on environmental orientation are highlighted.

While working with students of advanced training courses in the system of Institutes of Postgraduate Pedagogical Education of selected regions of Ukraine, namely Vinnytsia, Zhytomyr and Rivne, we conducted a survey of more than 200 teachers of natural sciences. With the help of questionnaires, the levels of formation of the main components of environmental competence in teachers were determined, the most effective forms and methods of their environmental work with students were identified.

During the implementation of Sorochynska Oksana's author's course "Training of future biology teacher for extracurricular ecological and naturalistic work with primary school students" a pedagogical experiment has been conducted for two years with the participation of about 400 students of the Faculty of Natural Sciences of Zhytomyr Ivan Franko State University.

3 Results and discussion

3.1 Higher Education standards and programs analysis

The importance of environmental knowledge, values, skills and corresponding competence at the professional level in the process of training of bachelors of natural sciences, biology and human health is recognized and supported at the state level in many countries, including Ukraine.

Thus, the Standard of Higher Education, specialty 091 "Biology" provides for the formation of two general (GC) and three special competencies (SC) of environmental orientation in students [21]:

GC01. Ability to realize his/her rights and acknowledge responsibilities as a member of society, as well as to accept and implement the values of civil society and the need for its sustainable development, the rule of law, human and civil rights and freedoms in Ukraine;

GC09. The ability to act socially responsibly and consciously in order to preserve the natural environment;

SC06. Awareness of the need to preserve biodiversity, protect the environment and conduct rational and effective environmental management;

SC09. Ability to analyze the results of the interaction of biological systems at different levels of the organization, their role in the biosphere and the possibility of their use in different sectors of the economy, including biotechnology, medicine and environmental protection;

SC10. Ability to demonstrate knowledge of mechanisms for maintaining homeostasis of biological systems.

In addition, obtaining the bachelor level qualification of specialty 091 "Biology" in the system of higher education involves the formation of 7 program learning outcomes that contribute to the sustainable development of society and understanding of the relationship between man and the environment, namely:

✓Understanding of the social and economic consequences of the introduction of the latest inventions and scientific research results in the field of biology within the professional activities;

✓Demonstration of skills needed to assess unpredictable biological problems and make informed choices;

✓Application of models, methods and data of physics, chemistry, ecology, mathematics in the process of learning and professional activity;

✓Adherence to the provisions of biological ethics, rules of bio-safety and bio-protection in the process of training and professional activities;

✓Ability to predict the effectiveness and consequences of environmental protection measures;

✓Application of methods for determining the structural and functional characteristics of biological systems at different levels of their organization in practice;

✓Ability to analyze data on diverse living organisms [21].

The standard of higher education of specialty *102 "Chemistry"* in addition to the general competence GC 01 provides for the formation of only one environmentally oriented program learning outcome: "Assess And Minimize Risks to the Environment While Carrying out Professional Activities" [24].

The standard of higher education of specialty *103 "Earth Sciences"* in addition to the general competence GC 01 (see 091 "Biology") provides for the formation of only three professional (special) competencies related to sustainable development, namely: 1) knowledge and understanding of theoretical foundations of "Earth Sciences" as a complex natural system; 2) the ability to apply basic knowledge of physics, chemistry, biology, ecology, mathematics, information technology, etc. in the study of the Earth and its geospheres; 3) the ability to monitor natural processes [25].

The standard of higher education in the specialty *101 "Ecology"* aims to develop such an integrated competence as the ability to solve complex specialized issues and practical problems in the field of ecology, environmental protection and sustainable use of nature. In the educational process the methods of environmental sciences are characterized by complexity and uncertainty of conditions" [22]. In addition to general competence, similar to the considered specialties, the standard provides for the formation of 13 special (professional) competencies and more than twenty program learning results in the field of ecology, environmental protection, environmental safety, environmental law, landscape management and biological diversity.

In the Draft Standard of Higher Education in the field of knowledge *01 Education / Pedagogy,* specialty 014 *"Secondary education* (by subject specializations)*"* in 2017 very few competencies and program learning outcomes aimed at forming the ecological competence of the future teachers [23].

Thus, for the specialty 014.05 "*Secondary education* (*Biology and human health*)" there is only one professional competence declared (ability to understand and implement the strategy of sustainable development of mankind in the process of teaching the students) and one program learning outcome (ability to understand and characterize the strategy of sustainable development, as well as to reveal the essence of the relationship between the natural environment and a human being).

For the specialty 014.06 "*Secondary education* (*Chemistry*)" - no (!) learning outcomes or other corresponding educational results are associated with sustainable development and formation of ecological worldview.

The training of geography teachers is the most nature-centric and environmentally-oriented. Moreover, for future geographers of the specialty 014.07 "*Secondary education (Geography)*" the formation of two subject competencies and five learning outcomes is provided. For example, a student must be able to:

✓describe the main mechanisms of functioning of natural and social territorial complexes, their individual components, as well as to classify the links, dependencies and interrelations between them; to know the causes, results and consequences of the processes occurring in/between them;

✓explain the changes that occur in the geographical environment under the influence of natural and anthropogenic factors; formulate the consequences and determinants in the context of the concept of sustainable development of mankind;

✓characterize natural landscapes and regions, explain their features and interconnections formed by geographical location and other geo factors;

✓understand global socio-geographical processes, be able to compile characteristics of the world's population, sectors and spheres of the world economy;

✓to characterize and evaluate natural conditions and resources, population and economy of Ukraine, its role and place in socio-geographical processes of the modern world [23].

After conducting the analysis of bachelor degree education programs (240 ECTS credits, 30 hours each) and curricula of various higher education institutions that train specialists in the above-mentioned specialties of natural and educational fields, we confirmed low and medium percentage of environmental educational components in their composition (Fig. 1).

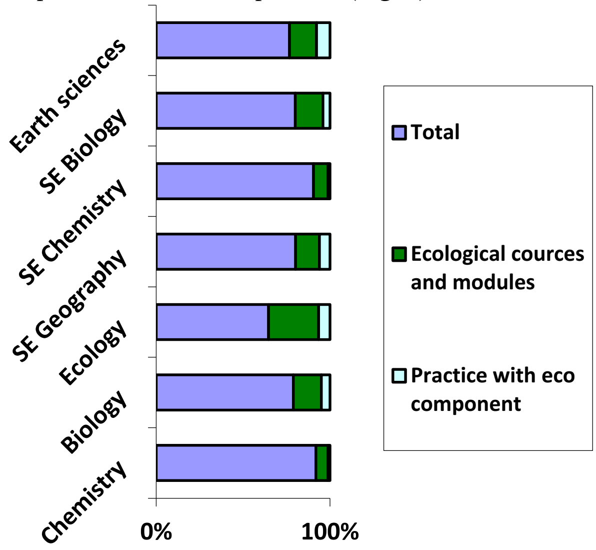

Fig. 1 Ecological **(**environmental) component of educational and professional programs (compulsory educational components), ECTS credits.

Thus, in the structure of the educational-professional program “Chemistry” at Zhytomyr Ivan Franko State University, the courses “General and Chemical Ecology” (3 credits), “Ecological Chemistry” (5 credits) are obligatory. In the curricula such courses as “Fundamentals of Chemical Technology” (6 credits), “Polymer Chemistry” (4 credits) contain separate topics aimed at developing the ecological worldview and competence of students. In addition, for several years in a row, among the selective educational components of the program students choose “Green Chemistry”, “Environmental Chemistry”, “Ecoanalytical Chemistry” courses.

In the educational-professional program “Biology” of the bachelor's level, the following subjects are obligatory for studying the discipline: “Bioethics and Biosafety” (4), “Ecology and Rational Use of Nature” (3). Some elements of ecological knowledge, including ideas about biodiversity, are given by the following courses: “Botany”, “Zoology” (12.5 credits), “Microbiology” (5), “Soil Science” (3), “Biogeography” (4), “Plant Physiology” (5 credits), etc. Among the selective educational components, which are traditionally chosen by the majority of biology students, there are many that have an ecological focus (“Ecology and Ethology of Fish”, “Systematics Of Chordates With The Basics of Ecology”, “Systematics of Higher Plants with the Basics of Ecology”, “Biomonitoring of Natural Waters”).

For applicants studying in the educational-professional program “Secondary Education (Geography)” at Zhytomyr Ivan Franko State University the following disciplines are obligatory to master: “Environmental Safety and Sustainable Development” (5 credits), “Landscape Ecology” (4 credits), and also many courses containing semantic modules of ecological direction, including “Geography of Soils With Bases of Soil Science” (4,5 credits), “Economic and Social Geography of Ukraine” (5), “Meteorology and Climatology” (5,5), “Landscape Science” (4.5); “Fundamentals of Social Geography” (4), “Methods of Extracurricular Work in Geography” (5.5), “Regional Economic and Social Geography” (4), “Geography of the World Economy” (4 credits). In addition, future teachers of geography often choose such selective educational components as: “Regional Ecology”, “Recreational Geography”, “Ecological Foundations Of Nature” and others.

In the process of training of students of the same specialty at the National Pedagogical Dragomanov University and Kherson State University, the curriculum also provides for more than 40 credits of normative disciplines, similar to the above-mentioned, which include content modules of environmental orientation. Selective disciplines are focused on the formation of ecological competence (“Anthropogenic Geomorphology”, “Ecological Hydrology”, “Management of Natural Resources” (3 credits each).

The Earth Science program at Kherson State University has significant potential for developing the environmental competencies of students. Thus, it includes compulsory educational components of the environmental professional competence and natural sciences, which contain environmentally oriented content of individual modules, namely: “Ecology” (3 credits), “Social Ecology” (3), “Life Safety and Environmental Safety” (3), “Environmental Monitoring” (3,5), “Modeling and Forecasting of the Environment” (3,5), “Organization of Ecological Management” (3), “Standardization of Anthropogenic Load on the Environment” (3), “Marine Geology and Geomorphology” (5), “General Geology” (3,5), “Meteorology and Climatology” (5), “Evolution of the Earth's Geospheres” (3), “General Hydrology and Oceanology” (4), “Landscape” (3), “ Geography of soils with the basics of soil science “(3,5). In addition, a significant part of the selective disciplines proposed for this specialty has an environmental focus: “Economics of Nature”, “Rational Use of Natural Resources”, “Recreational Geography”, “Environmental Marketing”, “Soil and Earth Protection” and others.

Formation of environmental competence of students of the educational program “*Secondary education (Chemistry)*” at National Pedagogical Dragomanov University is provided by a) normative disciplines: “Fundamentals of Chemical Safety” (6 credits), “Fundamentals of Production” (10), “Inorganic and Organic Toxicants” (6); b) disciplines of free choice of the student: “Environmental Chemistry” (6 credits) and “Modern Information Technologies in Ecological Chemistry” (4 credits).

In the educational training program for the specialty 014.05 *Secondary education (Biology and Human Health)* of the National Pedagogical Dragomanov University and Kherson State University, the formation of environmental competence of applicants is carried out during the study of normative disciplines “Ecology” and “Biogeography” (3 credits). Some components of ecological knowledge form the normative courses, namely: “Botany”, “Zoology” (11 credits), “Soil Science” (5), “Microbiology with the basics of virology” (4), “Plant Physiology” (5), “Evolutionary morphology” (3) and selective courses: “Plant Ecology”, “Animal Ecology”, “Dendrology”, “Mycology”, “Entomology” (3 credits each), “Animal Ethology”, “Ecological and valeological training for health activities”, “Biological systems” (4 credits each).

It is confirmed that the largest educational component of environmental orientation is the program “Ecology” for bachelors in all universities. So, at Zhytomyr Ivan Franko State University (ZIFSU) it includes 24 credits of educational and industrial practices, 3 credits of course works in various directions of ecology, 13 credits of educational courses containing modules of ecological direction, and also 94 credits for studying of various fundamental and applied ecological disciplines, among which there are: “Hydrology with the basics of hydroecology”, “Bioindication of environmental quality”, “General ecology”, “Environmental monitoring”, “Modeling and forecasting of the environment”, “Ecosafety and technoecology”, “Environmental legislation and environmental law”, “Economics of Nature Management”, “Landscape Ecology”, “Reserved Business”, “History of Ecology”, “General Ecology and Neo-Ecology”, “Organization of Management in Environmental Protection”, “Formal and Informal Environmental Education”, “Ecosystemology” and others. Among the elective educational components, students of ZIFSU mainly choose courses “Agroecology”, “Bioindication of Aquatic and Terrestrial Ecosystems”, “Ecological Tourism”, “Ecotoxicology”, “Ecophysiology of Animals”, “Ecological Biotechnologies” and others.

Students of ecological specialties at Kherson State University and National Pedagogical Dragomanov University have a very similar “core” of the educational program, which contains more than 90 credits of environmental disciplines. These include courses similar to the Zhytomyr Ivan Franko State University program, as well as educational components such as: “Standardization of Anthropogenic Pressure on the Environment”, “Environmental Impact Assessment”, “Urban Ecology”, “Environmental Inspection”, “Environmental Entrepreneurship”, “Environmental Marketing”, “Environmental Policy”, “Corporate Environmental and Social Responsibility”, “Countering Climate Change”, “Environmental Education and Science”, etc.

Thus, the environmental education component is best expressed in the training of future bachelors of ecology (more than 50% of credits for the study of required courses and practices), which is related to their professional qualifications. In the training of future biologists, bachelors of Earth Sciences (geologists, hydrologists, organizers of nature management, etc.), teachers of geography, biology, environmentally oriented disciplines (or individual modules) and practice account for about 24-33% of the workload. Educational training programs for chemists and future high school chemistry teachers have the lowest percentage of educational components aimed at the formation of environmental competence – less than 10% of ECTS credits.

3.2 Practical training as the means of forming students' ecological competence

An important component of students training is practice and internships. We believe that they play a leading role in shaping the environmental competence of future biologists, chemists, ecologists and teachers of natural sciences.

During productive practice in laboratories, which is mainly conducted in natural and artificial ecosystems, there is process of verification of the received theoretical ecological knowledge and its transition to practical one, as well as the formation of awareness of its efficiency and reliability. The internship provides students with the data on regional environmental problems in combination with the acquisition of experience of interaction with nature; formation of corresponding skills, which contributes to the emergence of a professionally sufficient level of environmental competence of chemists, biologists, ecologists. In addition, the environmental competence of future teachers of biology, basics of health, science, geography and chemistry is a necessary condition for the formation of appropriate personality traits in students [10; 11; 27].

Educational-professional training programs for students majoring in the specialties 102 “Chemistry” and 014.06 “Secondary education (Chemistry) provide practice in the basics of chemical production (3 credits), which must include analysis of environmental risks, environmental safety of a production, its impact on the environment.

Educational practices in zoology, botany, plant physiology and genetics (15 credits in total) at Zhytomyr Ivan Franko State University contribute to the formation of ecological competence of students majoring in 091 “Biology”. They are held mainly in the spring and summer, combining laboratory classes with excursions to natural biocenoses, reserves, sanctuaries, botanical gardens, zoos and more. Similar teaching practices are provided by the National Pedagogical Dragomanov University for future biology teachers in accordance to the training programs, namely: botany, zoology (9 credits), soil science (1.5 credits) and biogeography (1.5 credits).

For students majoring in 014.07 “Secondary Education (Geography)” educational program at Zhytomyr Ivan Franko State University provides 24 credits of practice, 6 of which are focused on internships in educational institutions, and others have a professional aim and significant potential for the formation of environmental competence, namely the following ones:

 https://doi.org/10.1051/e3sconf/202128009004

geology with the basics of geomorphology; soil science and landscape science; economic and social geography of Ukraine; i meteorology, climatology and cartography.

At the National Pedagogical Dragomanov University a similar set of practices for future geographers is also significant (12 credits included), namely it includes: complex (economic-geographical and physical-geographical) and educational practice in meteorology and climatology; geology; hydrology; geomorphology; soil geography with basics of soil science; cartography with the basics of topography.

Training of students majoring in 101 "Ecology" provides 24 credits of practical training at Zhytomyr Ivan Franko State University (bachelor degree), which includes the following: general ecology (7.5), ecosystem (7.5), landscape ecology (3) and industrial practice (6). Training of ecologists at National Pedagogical Dragomanov University also has 24 credits of practical training, including industrial practice (9 credits) and four educational practices – general environmental (3), secondary environmental (6), environmental monitoring (3), technological (3 credits).

Educational (out-of-laboratory in-the-field) practices of biological, ecological, geographical directions can be considered one of the most effective forms of ecological education of students, for they ensure the formation of culture of nature, behavior in natural ecosystems, a responsible attitude to nature, including emotional perception and rethinking the origin of objects and phenomena of the environment.

We agree with the point of view of many researchers [6; 17] concerning usefulness of undergoing the training practice of future biologists, ecologists, teachers of natural sciences in close proximity to the objects of nature, e.g. visiting reserves national parks, forests etc. to undergo However, only some of higher education institutions have stationary practice-oriented bases in protected areas. Thus, National Pedagogical Dragomanov University has a combined training and health complex in the Kolochava village on the territory of the Synevyr National Nature Park (Fig. 2). Uzhgorod National University's eco-training facility is located nearby, as well as the rehabilitation center for brown bears. Lake Synevyr Park also contains numerous natural monuments of regional importance where Red Book species of flora and fauna can be found (Fig. 3-5).

This ecological facility of national importance possesses a number of advantages, which are of a great importance for its use an outdoors educational base, including picturesque terrain, natural protection against environmental disasters, the availability of corresponding infrastructure which ensures satisfaction of all needs of the students in order to carry out effectively study of the fauna and flora of Transcarpathia, as well as possibility to monitor organized tourism and conduct environmental work in the national park, participate in the activities of the rehabilitation center for brown bears, while conducting research during internships. All this contributes to the formation of future natural sciences teachers' environmental competence and nature-centric worldview.

Fig. 2. Educational and health complex of National Pedagogical Dragomanov University, located in Kolochava village.

Fig. 3. Synevyr lake, biology students of Zhytomyr Ivan Franko State University during field practice.

Absence of property that may serve as the base for scientific or industrial practice makes it mandatory for the organization to conclude agreements on cooperation with other institutions of higher education (if such facilities are in their official possession), national parks, reserves or other corresponding legal entities. Combining several courses and / or several practices of one course (for example, botanical and zoological; zoology of invertebrates and chordates, etc.) is highly recommended. Therefore, practice leaders will get the necessary aid to effectively organize transportation, supplies provision, students' accommodation in order to carry out comprehensive environmental projects and conduct research. Students of the Faculty of Natural Sciences have the opportunity to undergo training and internships in Polissia, Drevlia, Rivne, Kaniv Nature Reserves, Synevyr National Nature Park through cooperation agreements with Zhytomyr Ivan Franko State University, which results in possibility to organize excursions to Shatsky lakes (Fig. 6, 7).

Natural science students and future teachers of biology and geography at Kherson State University are partially trained in the Askania-Nova Biosphere Reserve.

 https://doi.org/10.1051/e3sconf/202128009004

3.3 Students' field (out-of-laboratory) ecological-natural and research activities

Involvement of students of natural specialties in the research, environmental and ecological-naturalistic work during extracurricular activities plays and important role in the formation of their environmental competence. Moreover, this is a characteristic feature of modern education in Europe [11]. In our opinion, ecological and naturalistic activity involves mastering environmental knowledge by students/pupils, as well as gaining experience in solving corresponding problems, which accustoms young people to the organization, implementation of practical environmental and research work, formation of ecological culture of personality, social experience, basic skills of horticulture, floriculture, forestry, etc.

Thus, students majoring in "Ecology" together with associate professor of ecology and geography department of Zhytomyr Ivan Franko State University Ivan Khomiak volunter to participate in the international project "Polissia – wildlife without borders". The aim of the project is to study and preserve the biodiversity of Polissia region as one of the largest natural landscapes in Europe. The project activities are implemented in such areas as: research and monitoring; expansion of existing and creation of new protected areas, improvement of their management; restoration of environments (unique wetlands); raising public awareness of the nature of Polissia; improving the welfare of the population of the territory in environmentally acceptable ways (https://wildpolesia.org/ukr/?fbclid=IwAR1o69KDRH3Zt2GJT9hlgRm9P7fXlGpjydSQQoAEoPD9Zzor09N90KHuCPI). In particular, volunteers supported the initiative of the Ukrainian Society for the Protection of Birds to create a biosphere reserve under the UNESCO program "Man and the Biosphere" in the border areas with the Republic of Belarus, Zhytomyr and Rivne regions. Students of ecological specialties successfully competed with each other during the "Bird Day" campaign in team-based challenges, as well as monitored the nests of black storks *Ciconia nigra* in the Polissia Nature Reserve together with scientists.

Students' participation in ecological forums, projects, and flashmobs proved to be quite effective ecologically oriented extracurricular work. For example, students of ecological specialties and the educators of the Faculty of Natural Sciences of ZIFSU joined the International Forum "Environmental Ambitions of Youth" (February 27, 2020, Kyiv, Verkhovna Rada).

Future chemists, ecologists, and biologists have repeatedly participated in the "Climate Collage" game, which was developed by Cedric Ringenbach in order to give young people a deep understanding of the relationships within the ecosystems and the impact of a human being on the environment. The game was first presented at the UN Climate Conference in Madrid in 2019 and since then it has been successfully used as an interactive method for the formation of environmental competence of young people.

They supported the international movement "Let's Do It, World", cleaning the historic part of the city of Zhytomyr, as well as participated in the "World Cleanup Day" flash mob (September 19, 2020) (Figs. 8-10).

Fig. 8. Students and educators of ZIFSU visiting "Ecological Ambitions of the Youth" forum in the building of Verkhovna Rada of Ukraine.

Fig. 9. "Ecological collage" game, faculty of natural sciences of ZIFSU.

The effectiveness of ecological and naturalistic work of young people is confirmed by research conducted in the framework of the introduction of university selective discipline "Methods of ecological and naturalistic activity in general schools and out-of-school educational facility" (National Pedagogical Dragomanov University, Olga Tsurul) [27] and the author's course "Training a future biology teacher for extracurricular environmental and naturalistic work with primary school students" (Zhytomyr Ivan Franko State University, Oksana Sorochynska) into the educational environment [20].

Fig. 10. Participants of «World Cleanup Day» campaign (Zhytomyr).

In particular, the program of the course "Training of future biology teachers for extracurricular ecological and naturalistic work with primary school students" provided for the introduction of traditional and innovative forms, methods of organizing ecological and naturalistic work into the educational process in order to improve the quality of formation of ecological competence of students, therefore an author's program, methodical recommendations and a manual "Ecological and naturalistic work at school" were developed and implemented. The author's program exploits such forms of work as a conference, development of an ecological project, ecological excursion and field hike, ecological expedition, ecological training, quest. Among the innovative methods used, there are the method of graphic and research works, business- and simulation games, dramatization games, case studies, interactive methods ("Fish Bowne", "Bloom's Cube", "Mental Map", "Brainstorming", etc.).

The experimental work lasted for 2 years and involved the ascertaining and forming stages of the experiment. At the initial stage, two groups of students were identified: control group (CG), which included 196 students, and experimental group (EG) with 198 participants.

To create a holistic picture of the formulated aim of the research, a survey was conducted, which allowed to identify a list of forms of ecological and naturalistic work. Prior to the implementation of the author's program, the level of students' awareness of the forms of such work was at a fairly low level. About half of the respondents mentioned forms of work that are theoretical in nature and have little effect on the formation of environmental competence (environmental exhibitions, holidays and competitions, writing essays, environmental campaigns, environmental-themed evenings and weeks, "What? Where? When?" intellectual club, CCS club, etc.). Only 19% of students noted the organization of environmental lectures and conferences, round tables; "blue" and "green" watch patrols, school forestry, ecological museums and theaters, ecological trails; performance of research and experimental works on school geographical and meteorological platforms, ecological laboratories research work; training and substantiating research projects.

However, in contrary to the students, teachers-practitioners from Zhytomyr, Vinnytsia and Rivne regions have given a particularly different statistical gradation of the effectiveness of applied forms of ecological-naturalistic work in the formation of ecological competence:

1) ecological excursions and expeditions (58,7%),
2) ecological campaigns (56,1%),
3) ecological trail experiments and observation (54,8%),
4) eco-trainings (53,5%),
5-6) empirical experience while working at the pet's corner or conducting a field research at the out-of-laboratory research site (по 49,6%),
7) eco-scientific projects (35,1%),
8) ecological contests (19,8%),
9) ecological exhibitions (17,2%),
10) eco-fashion contests (15,9%),
11) collecting eco-stuff, conducting eco-holidays, flashmobs etc. (8,9%) [10].

The results of our survey of teachers of natural sciences correlate with the research of other scientists [20]. According to the data collected, the most effective forms of environmental activities at school are the following: preparation and substantiation of environmental projects (over 50%), seminars and conferences (42.3%); business- and role-playing games (36.5%); organization of cooperative creative work and educational environmental activities related to certain international and state projects (32.7%); implementation of research and exploration work, excursions, ecological trails (26.9% each); conducting lessons on sustainable development and environmental issues (26%) [10].

However, teachers mostly introduce forms of theoretical work and to a lesser extent are engaged in research work, observations and experiments on the ecological trail, conducting ecological excursions and expeditions, practical work in wildlife and educational areas, training, which indicates an unfortunately low level of their empiric involvement (Fig. 11).

This fact can be explained and justified by the insufficient level of eco-oriented training during their studies at the universities, as well as lack of time, unwillingness to carry out the specified form of work, which result in general weakening of students' interest in learning.

The formation of students' environmental competence within the author's program was carried out on the basis of the developed model of preparation for ecological and naturalistic work. Identification of the level of environmental competence of students (initial, intermediate, high) was carried out according to 4 criteria (motivational-target, cognitive, practical, personal-reflexive), which correspond to its structure. The generalization of the results of the experiment was conducted using the method of score scales, which allowed to calculate the level of formation of environmental competence of students and the dynamics of change [20].

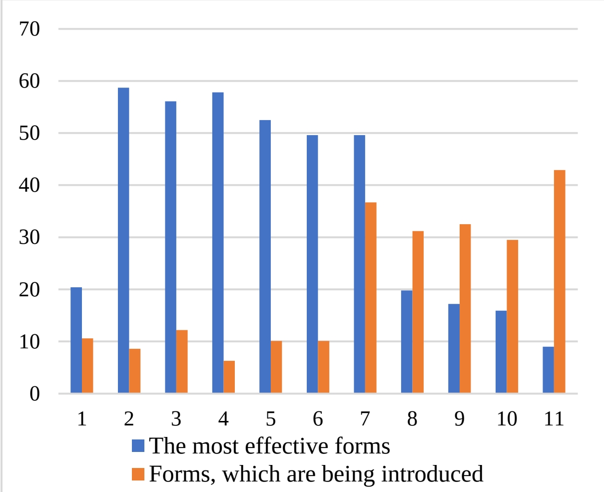

Fig. 11. Effective forms of environmental and naturalistic work that contribute to the formation of ecological competence of students (according to the results of a survey of teachers, %).

Comparative results of identification of levels of formation of environmental competence on motivational-target criterion of control and experimental groups are specified in fig. 12.

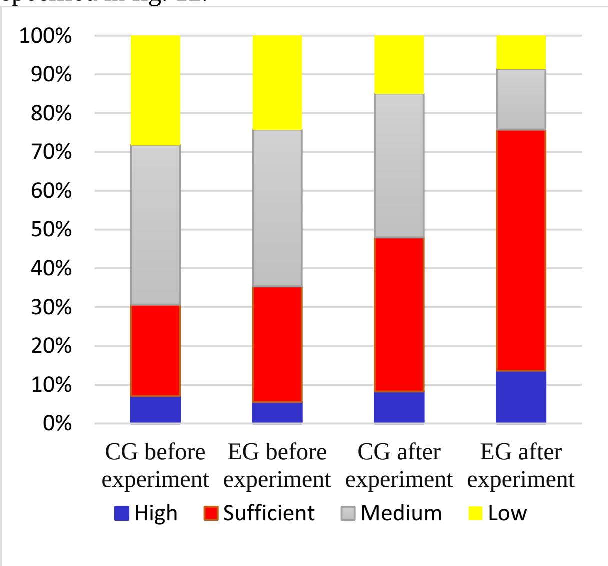

Fig. 12. Levels of formation of environmental competence of students on a value-motivational component according to results of experiment.

Cognitive component of the formation of environmental competence involved the gaining a set of knowledge (psychological-pedagogical, professional-environmental and naturalistic, methodological, organizational-methodological). Each of the knowledge groups contained a list of indicators for which the assessment was carried out.

The analysis of the results of the observational stage of the experiment showed a mostly low level of formation of students' ecological knowledge. Identifying the indicators of the cognitive component of the formation of environmental competence of students of control and experimental groups by cognitive criteria are shown in Fig. 13.

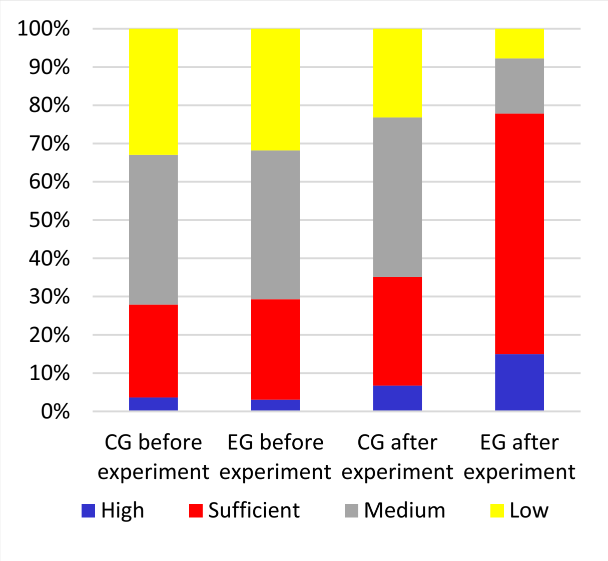

Fig. 13. Levels of formation of environmental competence of students on a cognitive component according to experimental results.

We observed significant changes in the results of cognitive component formation in the experimental group (EG) compared with the data of control group (CG). In particular, a high level of formation of environmental competence was shown by 14.66% of EG students, sufficient – 61.63%, medium – 14.15%, primary – 7.57%. In turn, the distribution of CG students' answers was as follows: high level – 6.73%, sufficient – 28.38%, medium — 41.72%, low – 23.16% (Fig. 13).

Practical (activity-based) component included such groups of skills as gnostic, designing, constructive, organizational, applied. Among the gnostic skills we singled out the following: the ability to conduct scientific research, monitor results of scientific activity, analyze scientific literature, etc. Designing skills are identified as the ability to: model forms and methods of ecological and naturalistic work; plan work and design the content of ecological and naturalistic work, etc. Constructive skills include the ability: to construct the content of ecological and naturalistic work, to introduce the most effective forms and methods; to have strategies for the formation of ecological competence, etc. Organizational skills are referred as the ability to carry out research activities; to manage the work of organizations of ecological and naturalistic orientation; to conduct ecological and naturalistic propaganda, and others. Practical (applied) skills are the application of methods of diagnosis of ecological and naturalistic abilities, organization of excursions, hikes, the ability to use ICTs, designing, modeling, etc. The level of ecological competence in the activity component was carried out on the basis of specially designed questionnaires, thus the reliability of the results was checked using the method of O. Smirnov, using Student's t-test. Indicators of the practical criterion after the introduction of the author's course differed significantly in the experimental group compared with the control (Fig. 14).

Personal-reflexive component of the formation of environmental competence of students involved the development of certain qualities and abilities (love of nature, erudition, diligence, perseverance, creativity, observation, environmental activity, etc.).

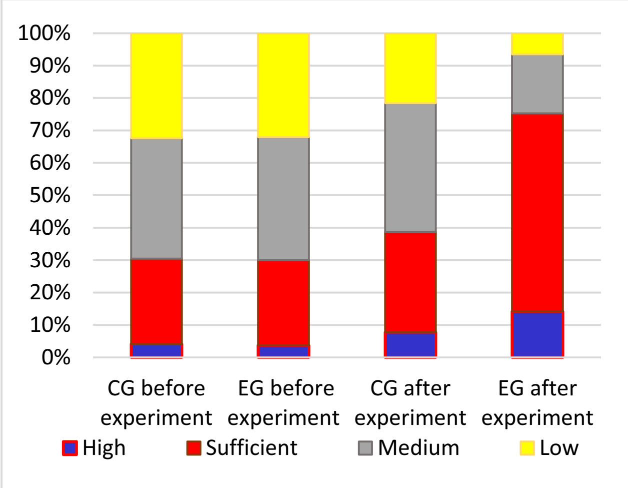

Fig. 14. Levels of formation of environmental competence of students on practical component according to the results of the experiment.

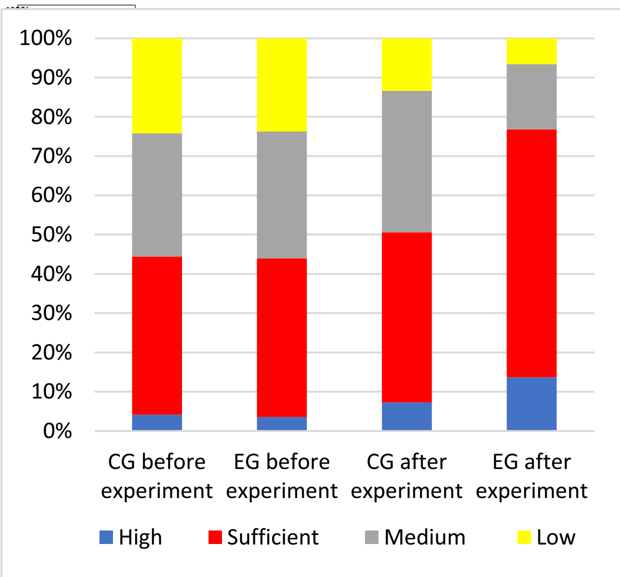

Fig. 15. Levels of formation of environmental competence of students on a personal-reflexive component according to results of experiment.

Analysis of the results of the formation of ecological competence in process of introduction of the author's program "Training of future biology teachers for extracurricular environmental and naturalistic work with primary school students" showed the effectiveness of its implementation in the educational process. After the formative stage of the experiment, the levels of environmental competence of students in the experimental groups were distributed as follows: high – 15.03% of students; sufficient – 62.01% of respondents; medium – 16.66% of participants; low – 7.31%. In the control group the indicators are: high level – 7.51%, sufficient – 35.60%, medium – 38.63%, low – 18.27%.

Thus, the generalized results of formation of environmental competence of students in experimental groups by results of ascertaining and forming stages of experiment show positive dynamics on all indicators and components (table 1, fig. 16) that testifies to efficiency of the introduced author's program.

Table 1. Dynamics of levels of environmental competence of students according to the results of the experiment.

Level of formation of environmental competence	**Control Groups (CG)**			**Experimental Groups (EG)**		
	Initial stage of the experiment, ,%	Final stage of the experiment, %	Dynamics, %	Initial stage of the experiment, %.	Final stage of the experiment, %	Dynamics, %
High	4,5	7,5	3,0	3,9	14,0	10,1
Sufficient	27,9	35,6	7,7	30,4	62,0	31,6
Medium	35,9	38,6	2,7	37,5	16,7	-20,8
Low	28,6	18,3	-10,3	28,2	7,3	-20,8

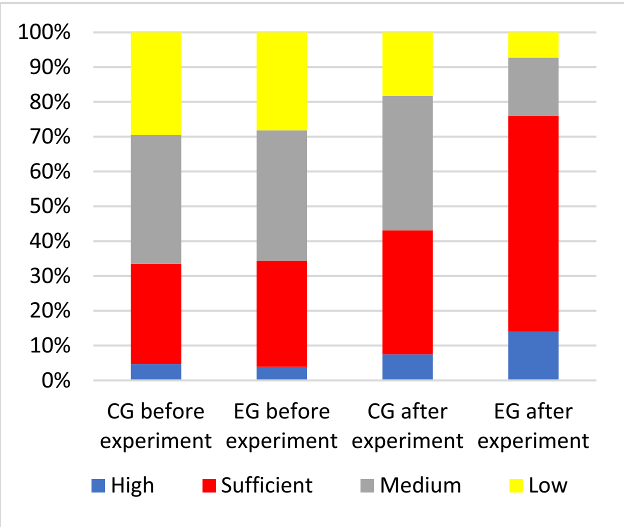

Fig. 16. Dynamics of levels of environmental competence of students according to the results of ascertaining and forming stages of experiment.

4 Conclusions

Thus, our research indicates that the need to implement the concept of sustainable development highlights the issues of formation of ecological (environmental) competence in students of natural sciences within the educational environment of the universities. In turn, the formation of environmental competence is carried out by acquiring environmental education through interactive technologies, innovative forms and methods of organizing the educational process, as well as during eco-oriented extracurricular activities.

An analysis of the ecological education component of training of students of natural sciences confirmed the fact that its best manifestation is found in the content of education of future bachelors of ecology (over 50% of credits are directed to mastering the required courses and undergoing corresponding types of practice). In the process of training of future biologists, specialists in the field of Earth sciences, including teachers of geography and biology environmentally oriented disciplines (or individual modules) and practice account for about 24-33% of the entire workload. Educational training programs for chemists and future chemistry teachers have the lowest percentage of educational components aimed at the formation of environmental competence (less than 10% of ECTS credits), which significantly affects the level of formation of their ecological environmentally-oriented competence.

It is proved that the leading role in the formation of environmental competence of students of natural specialties is played by interactive practice-oriented forms and methods of teaching, as well as training and production practices, which is an essential component of their professional training.

The positive impact on the level of environmental competence development of students of natural specialties produces their involvement in research work, as well as active participation in environmental and ecological-naturalistic activities in extracurricular time, which is evidenced by the generalized results of the ascertaining and formative stages of our experiment.

The following fields are considered the most perspective for our further research: development and implementation of innovative technologies of extracurricular ecological and naturalistic work of students; finding theoretical and practical solution to the problem of integrating knowledge from different disciplines in the process of environmental education; analysis and implementation of foreign experience in the formation of environmental competence of youth; involvement of students of natural specialties in the activities eco-oriented associations for children and youth.

Abstract. In modern conditions for complex thermal power facilities, the issue of developing methods for predicting equipment failures is especially relevant. Methods based on the intellectualization of diagnostic systems and allowing to obtain predictive models based on the use of both current data received in real time from measuring equipment and retrospective information are considered promising. Intellectualization of the system in terms of the ability to learn allows to quickly adjust the parameters of forecasting models under changing conditions of equipment operation, to determine new deadlines for scheduled repairs and minimize equipment downtime. A limitation of the use of methods is the incompleteness of failure statistics, ie when equipment failures are rare or non-existent. Such diagnostics of energy equipment, especially thermal power facilities, contributes to a more environmentally friendly production.

1 Introduction

Modern technical facilities, including thermal power facilities, are complex systems built of different components – mechanical, electrical, electronic, etc., combined with the tasks of control of a particular process. Distinctive features of functioning of objects of heat power engineering are work in the conditions of irregular dynamic loadings applied practically to all elements of its design [1-3]. These loads can occur both due to internal factors and as a result of the influence of other equipment operating nearby [4].

At present, a large number of complex thermal power plants (nuclear and chemical reactors, turbines, powerful boilers, various furnaces for smelting metal, etc.) are equipped with automated control systems for technological parameters [5-7]. The controlled parameters, in addition to information about the flow of technological processes, also contains information about the current state of the equipment, the appearance and development of various faults [8-10]. Analysis of changes in these parameters, performed after accidents, unscheduled equipment stops, usually shows that there were signs of malfunctions that caused the accident or stop, long before the incident [11-13]. Thus, there is a fundamental possibility to identify abnormal conditions (faults) before they caused the accident and, thus, to prevent the accident or significantly reduce its consequences. Such cases are known to any operator who controls the technological processes of complex thermal power facilities (CTPF), but they are rare, exceptional due to limited human capabilities in the rapid processing of large amounts of information and lack of prior analysis of processes in case of failure. Automated systems for collecting and processing information significantly expand both the operator's ability to identify faults and allow to automate the process of their detection, ie diagnosis [14,15]. For this purpose it is necessary to have a technique and corresponding diagnostic algorithms which use the information from sensors of technological control [16]. Such techniques and algorithms can significantly increase the effectiveness of CTPF diagnosis.

One of the important tasks of diagnostics of power equipment is to minimize the impact of power equipment on the ecological state of the environment. In this case, it is necessary to solve the following tasks:

- research and minimization of the negative impact on the environment at all stages of production, transmission and consumption of different types of energy [17-22];
- implementation of activities for the conduct of environmental studies, including the assessment of the impact on the environment [23-25];
- utilization / neutralization of energy equipment waste after completion of operation [26-30];
- participation in programs for the development of renewable energy sources, taking into account the application of the world practice of using market mechanisms for their support on the basis of "green" tariffs [31-34];
- formation of environmental requirements for the development of modern power equipment [35];
- analysis of developments and implementation of techniques, standards, criteria, requirements in the

https://doi.org/10.1051/e3sconf/202128009005

field of environmental protection, environmental safety and rational use of natural resources [36-41];

- development of educational programs in the field of environmental safety in the production, transmission and consumption of electricity etc [42-46].

Thus, the diagnostics of power equipment should become one of the mandatory steps in improving the environmental friendliness of enterprises in the fuel and energy complex.

2 Anomaly detection based on neural networks

The method of detecting anomalies based on neural networks includes two stages: 1) the neural network learns to recognize classes of normal behavior in a training sample; 2) each instance of the instance comes as an input signal to the neural network. A neural network-based system can recognize one or more classes of normal behavior.

Replicative neural networks are used to find anomalies by recognizing only one class [47]. Deep Learning neural network technology has also been used successfully to solve this problem [48].

Various methods can be used to search for anomalies [49-51], the advantages and disadvantages are presented in the Table 1.

Machine Learning is a class of methods of artificial intelligence, which is characterized by indirect problem solving, and learning in the process of applying solutions to many similar problems [52]. In the process of constructing such methods can be used mathematical statistics, numerical methods, optimization methods, data mining, probability theory, graph theory.

Using machine learning possible the study of patterns in the data, which are then used to detect abnormal behavior. Machine learning tasks are usually divided into the following categories depending on the availability of a training “signal” or “feedback” available to the training system.:

– learning with a teacher using “reaction-stimulus” examples;

- partial training with a teacher;
- active learning;
- reinforced training;

– learning without a teacher, suitable for tasks in which objects are described in detail and it is necessary to establish internal relationships between objects.

Next, deep neural networks will be considered as methods used to detect anomalies.

Table 1. Advantages and disadvantages of anomaly detection methods.

Method	Advantages	Disadvantages
Statistical analysis [52-55]	Lack of requirement for a priori information on signs of anomalies, which makes it possible to detect zero-day vulnerabilities against which protective mechanisms have not yet been developed	The difficulty of determining the threshold for optimal detection of anomalies, the impossibility of identifying anomalies as a result of malicious actions similar to normal actions or work and the requirement of statistical distributions in the absence of all elements of the process
Machine learning [56]	Improved system based on prior knowledge	High computational costs, as well as the complexity of adaptation to the subject area
Artificial neural networks [57]	Resistance to inaccurate input, as well as independence from the availability of information about the dependencies of the examples of input data	Complex and long training of neural networks, as well as demanding on the size of the training sample
Genetic algorithms [58]	Works well in solving large-scale optimization problems. Uses two decision mechanisms: deterministic and probabilistic. Uses multiple search space points	The complexity of the selection rules for selecting the best solutions
Hybrid methods [59-62]	The most flexible, as it allows to reduce the impact from the disadvantages of one method taking advantage of another	

The advantage of deep neural networks is the automatic selection of these important features. An inverse error propagation algorithm based on the gradient descent method is used to train neural networks [63]. In a deep neural network with several hidden layers, an error is calculated that is transmitted from one layer to another. In the first stage, the value of the error at the output of the neural network is calculated, for which the correct values are known. Then the error at the input to the output layer of the network is calculated, which will be used as an error at the output of the hidden layer. Therefore, the calculation continues until the error on the input layer is known. However, this algorithm is often not effective when the training sample is large, because it takes a long time to process all its elements. In practice, the method of stochastic gradient descent or its modification is most often used to train neural networks [64,65].

However, the error back propagation algorithm is not sufficient for effective deep learning due to the problem of the vanishing gradient [66]. This problem is solved by the architecture of the neural network with long short-term memory (LSTM) [67,68]. Such networks contain special types of nodes that allow to remember values for a long time. The LSTM network unit contains a special neuron that is used as a memory element (Fig.1).

The output of a neuron is connected to its own input with a single weight. As a result, the value in the neuron is rewritten at each stage and thus stored. Neuron control is performed by three valves: input, output and forgetting valve. When the inlet valve is open, the value at the inlet is written to the memory cell. If the inlet valve is closed, the inlet signals do not affect the contents of the cell. An open outlet valve allows to read values from a cell. When the value is no longer needed, it can be erased with the forget-me-not valve. Valves are connected to other nodes of a neural network which in the course of training define when it is necessary to open or close this or that valve.

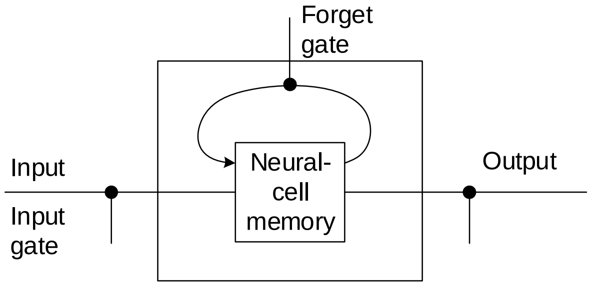

Fig. 1. LSTM network block diagram [67].

Through these networks cells LTSM can determine the importance of the events that occurred thousands of discrete time steps back and remember these events. Recurring networks previously used could remember the event for no longer than ten time steps [69].

The choice of neural network architecture is based on several factors. First, the sensors generate highly correlated multidimensional time series. In addition, these time series are aperiodic and synchronous (aligned in time), with fast (long-term) and slow (short-term) subprocesses. Under these conditions, conventional neural networks of direct propagation usually show poor results. An accurate data-driven predictive model can be developed using a neural network with LSTM cells [70].

Since not all time series can be predicted [71], it is possible to use an additional method of finding anomalies – autocoder, which allows to apply training without a teacher during using the method of reverse error propagation. A synchronous architecture was chosen for the autocoder, among the advantages of which is the possibility of using the streaming mode of data processing and a relatively smaller number of neural network parameters compared to other architectures.

3 Neural network architecture for anomaly prediction

3.1 The process of detecting anomalies

The process of detecting anomalies consists of the following stages:

1. Calculate the estimate of the anomaly of some observations or subsequences of a given time series using the detection method.

2. The obtained estimates are used to calculate estimates of anomalies of test time series. This application is performed in different ways, for example: (1) the average value of all anomaly indicators, (2) the average value of the upper anomaly estimate, (3) the average value of the logarithm of the anomaly estimates, (4) the anomaly estimates exceed the threshold, etc.

Test time series with the assessment anomaly that exceeds a threshold, denoted as abnormal.

The block diagram of failure forecasting is developed (Fig. 2) and the algorithm of detection of anomalies which consists of two parts is offered: forecasting and detection.

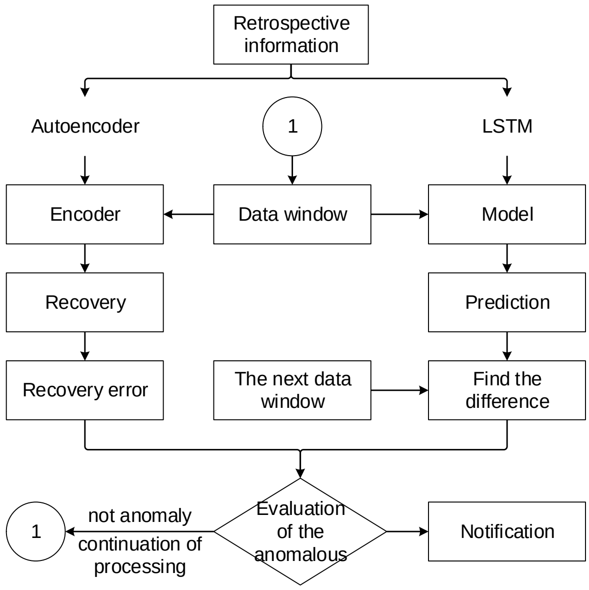

Fig. 2. Block diagram of the neural network for predicting anomalies.

First, all time series (collected at different points in time statistical material on the values of any parameters of the studied process) are divided into sequence levels of length w, namely $X(i) = x(j), x(j+1), \dots, x(j+w-1)$, where i – the sequence number, $j = w(i-1)+1$ – the number of the first countdown in the sequence. At the prediction stage, the values for the next sequence $X(i+1)$ are selected using the data of already performed measurements $X(1), X(2), \dots, X(i)$.

All data points in the presented data set have the same time grid and have significantly different absolute values. To reduce these variations and combine different dimensions, the normalization transformation is applied to each dimension separately:

$$x_i^{*(j)} = \frac{x_i^{(j)} - \bar{x}_i}{\sigma_i}$$

where $i = \overline{1, n}$; $\bar{x}_i$ and σ_i – mean and standard deviation for each measurement.

The detection stage is based on the search for time points, where the root mean square error between the measured values of $X(i+1)$ and the predicted $X'(i+1)$ becomes greater than the pre-calculated threshold.

To detect anomalies, a recurrent neural network with a long-term memory architecture and an autoencoder were chosen, which allows to apply training without a teacher during using the method of error back propagation. A synchronous architecture was chosen for the autoencoder, among the advantages of which is the possibility of using the streaming mode of data processing and a relatively smaller number of neural network parameters compared to other architectures.

Finding neural network parameters is an iterative task. Most often, developers select the optimal values of the structural parameters of the network and the size of the training sample, based on personal experience and repeated trials and errors. Therefore, the structural parameters of the network and the size of the training sample may not be optimal in terms of some function of the approximation error.

Several main rules for neuronal isolation have been presented, for example, the number of hidden neurons should be less than twice the size of the input layer [72,73]. Several statistical methods have also been developed, some of which are presented in Table 2. Although such methods are proposed, they are difficult to implement using commercial software packages. Typically, these recommendations are applicable to the specific cases of a particular network topology.

Table 2. Review of methods for selecting the number of hidden neurons [74].

Method	Number of hidden neurons
Li et al. method [75]	$N_h = (\sqrt{1+8n} - 1)/2$
Tamura and Tateishi method [76]	$N_h = N - 1$
Fujita method [77]	$N_h = K \log\|P_c Z\|/\log S$
Zhang et al. Method [78]	$N_h = 2^n/n + 1$
Jinchuan and Xinzhe method [79]	$N_h = (N_{in} + \sqrt{N_p})/L$
Xu and Chen method [80]	$N_h = C_f (N/d \log N)^{0.5}$
Shibata and Ikeda method [81]	$N_h = \sqrt{N_i N_o}$
Hunter et al. Method [82]	$N_h = 2^n - 1$
Sheela and Deepa method [83]	$N_h = (4n^2 + 3)/(n^2 - 8)$

The amount of training set is also a parameter that optimizes the quality of neural network model.

The greater the amount of training set, the greater the amount of memory required to store it, time spent on training the neural network and gather information about the object. A training sample with a small amount of data is not informative enough to characterize the behavior of an object with acceptable quality. This leads to the fact that the network is often unable to predict the behavior of the object outside the examples of the training sample.

Insufficient number of neurons in the hidden layer will not allow to fully approximate the behavior of the object, and the prediction error will be large. But the more complex the neural network, the more time it takes to learn and work on the task. The predictive power of the network may also decrease due to the effect of retraining. The neural network will show insignificant or insignificant details in the studied dependence, such as noise, the output vector will change significantly with small deviations of the input vector and the neural network will not be able to generalize – prediction of the output vector with input data not included in the training sample.

Based on the above information, the decision to make a variation of the neural network training parameters:

- training periods are 1, 4 or 12 months;
- number of hidden layers – 2 or 4;
- the number of hidden neurons in the first layer – 8, 15, 20, 24, 30, 45, 60, 90;
- the number of hidden neurons is halved in each subsequent layer.

3.3. Neural network training

A total dataset (retrospective data) of 15,120,000 measurements over 35 months from more than 107 sensors [83] has the following values:

- date in the format – day/month/year;
- time in the format – hour: minute: second;
- densor ID;
- sensor_measure temperature value.

Sensors generate highly correlated multidimensional time series, which are aperiodic and synchronous (aligned in time), have multiscale processes, fast (long-term) and slow (short-term) subprocesses.

Each created model is evaluated on the basis of a graphical overview of the model trend. Models are evaluated using the following hierarchical criteria:

- suitability of the model on educational data;
- suitability of the model on the data for monitoring the normal state;
- detection of anomalies.

To be considered reliable, the model must meet all of the above criteria. The evaluation criteria are hierarchical, as each model must meet the previous criteria before evaluating the next criterion.

Table 3. Evaluation criteria forecasting models.

Model criteria	Suitability of the model during the training period or monitoring of normal condition	Detection of anomalies
Very bad ($0 < R^2 \leq 0.2$)	Models with a constant very significant deviation from the measured values or with a clearly inconsistent forecast	Unable to detect anomalies model is not reliable
Bad ($0.2 < R^2 \leq 0.4$)	The models follow the measured trend to some extent, but are characterized by constant significant deviations and periodic very significant deviations from the measured values	Unable to detect anomalies, the model follows the trend measured in the same or a higher level
Satisfactory ($0.4 < R^2 \leq 0.6$)	Models can record the dynamics of the process, but are characterized by constant slight deviations and periodic significant or very significant deviations	Insignificant indicators of anomalies, the model follows the measured trend
Good ($0.6 < R^2 \leq 0.85$)	Most of the time, the models have an accurate forecast with frequent minor deviations	Indicators leading to a more detailed analysis
Very good ($0.85 < R^2 \leq 1.0$)	The models follow the measured trend and have only a few slight deviations from the measured values	Clear indication of anomalies

Validation and verification of the used neural network models was performed. The criteria for evaluating forecasting models during network training based on the coefficient of determination are given (Table 3).

In Table 3, the coefficient of determination R^2 of the model of the dependence of the predicted values on the measured values is determined by the formula:

$$R^2 = 1 - \frac{\sum_i (y_i - f_i)^2}{\sum_i (y_i - \bar{y})^2},$$

where y – predicted values, f_i – current values, $\bar{y}$ – average value.

Determination coefficients R^2 together with scattering graphs provide a fairly simple tool for estimating model prediction. However, it should be emphasized that R^2 is a relative indicator of the adequacy of the model (test and training samples are representative, the network structure is not redundant) and should not be used only as an indicator of efficiency.

Since in most cases the result of errors depends on the shape of forecasting errors are more commonly used performance based on the likelihood of true or false prediction. Assume that for each set of test data, the predicted probability of success $f(x_i)$ is compared with a fixed threshold *C*. If the probability is greater than *C*, it was assumed that the model successfully predicts; otherwise it was believed that the prediction is unsuccessful. The result of this procedure of comparing the true and predicted values of the dependent variable for *n* observations in the test data set can be presented in the form of a contingency table (table 4).

A simple indicator of the effectiveness of the model is accuracy, the proportion of correct predictions in the entire data set of testing:

$$ACC_C = \frac{TP_C + TN_C}{n}.$$

Metrics such as precision and completeness are also used to evaluate the model algorithm. Precision within a class is the proportion of objects that actually belong to this class relative to all objects that the system has assigned to this class:

$$Precision_C = \frac{TP_C}{TP_C + FP_C} = \frac{TP_C}{P_C}$$

Recall of the system – a lot classifier found objects belonging to the class with respect to all objects of this class in the test sample:

$$Recall_C = \frac{TP_C}{TP_C + FN_C} = \frac{TP_C}{S_C}$$

The resulting accuracy of the classifier is calculated as the arithmetic mean of its accuracy for all classes. The same with completeness. Technically, this approach is called macro-averaging.

The average harmonic value of precision and completeness determines the F-score:

$$F_c = 2 \cdot \frac{Precision_C \cdot Recall_C}{Precision_C + Recall_C}$$

This formula gives the same weight of accuracy and completeness, so the F-score will fall equally with decreasing precision and recall.

Table 4. Contingency table.

	True class: Positive	True class: negative	Measures
$f(x) > C$, predicted class: positive	TP_C	FP_C	P_C
$f(x) \le C$, predicted class: negative	FN_C	TN_C	N_C
Measures	S	F	n

As a result, it was found that the performance of models with a training period of 12 months differs the most (Fig. 3). In the figure, the dotted lines are divided into three periods: training, normal operation and detection of anomalies.

Table 5 and Figure 4 present the results of the calculation of precision, recall, F-score and efficiency of the 2C8 model.

Table 5. Contingency table for model 2C8.

	0	1	Accuracy	Macro avg	Weighted avg
Precision	0.98	0.84	0.97	0.91	0.97

As a result, it is established that in order to diagnose the condition of the service station it is necessary to substantiate and build a model that provides detection of an anomaly with a minimum number of false alarms during operation in the normal state.

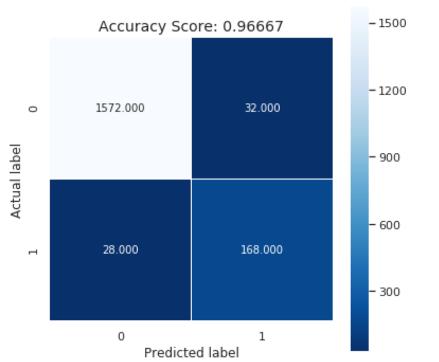

Fig. 4. Graphical representation of the contingency table for the 2C8 model.

4 Model testing results

It is accepted that during using models, they must be rated “good” or “very good” to be considered accurate enough for use in the diagnostic process (Table 3).

It is shown that 13 of the 96 created models meet the established criteria. Model 2C8 with a training period of 12 months, 30 automatically selected independent variables, 4 hidden layers and 90 hidden neurons showed very good results and was chosen as a reference model (Fig. 5). This made it possible to predict the anomalous state of the service station with a coefficient of determination of 0.965 based on the measurement of the surface temperature of thermal power equipment, which can be used as an indicator of the technical condition.

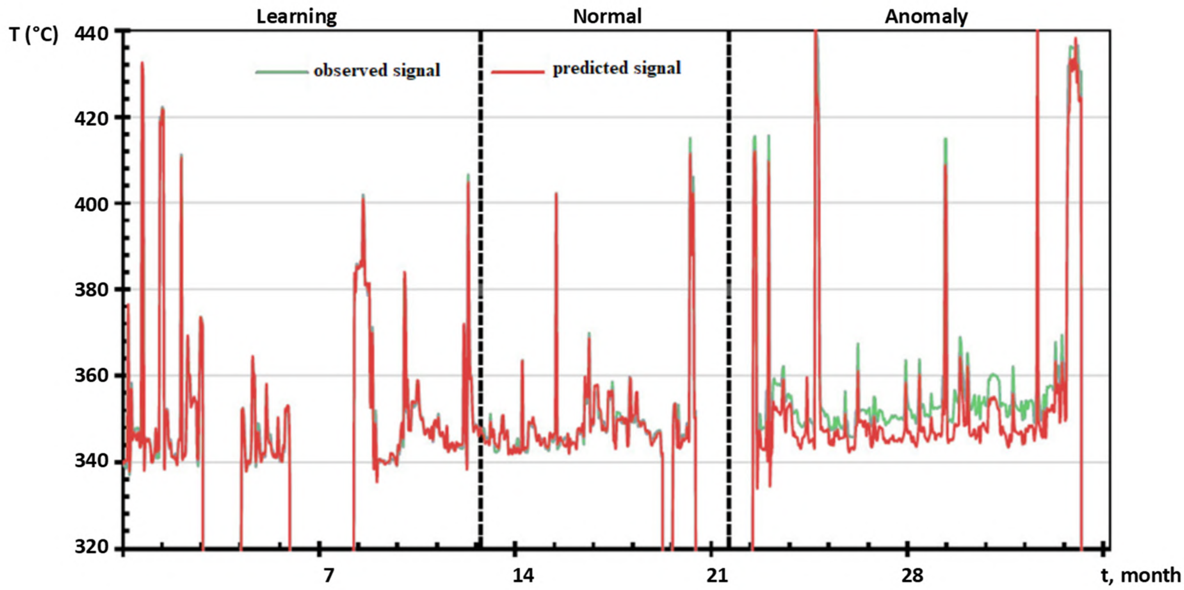

Fig. 5. The results of direct measurements (according to kaggle.com) and the predicted surface temperature of the boiler based on the reference model 2C8 for 35 months. Dotted lines indicate three periods: training, normal operation, detection of anomalies.

According to the results of testing the diagnostic system, it was found that models with a training period of one month show similar behavior to each other, regardless of other learning parameters. These models are characterized by satisfactory adaptation to these exercises. It is shown that the training period of one month is too short for the network to learn about the full features of the process.

It is shown that models with a training period of 4 months have better forecasting characteristics. Models 1B5–1B7 and 2B5–2B8 with 30 hidden neurons in the first hidden layer have relatively better overall R^2 values at all stages of training, monitoring and detection of abnormalities. These models are the group with the best performance, as they account for 7 out of 13 reliable models.

The accuracy of the models increases with the addition of two hidden layers. The set of variations among these models and the influence of the number of hidden neurons on the efficiency of the model are analyzed.

5 Conclusions

The structure of the neural network was developed on the basis of stacking algorithms of the recurrent neural network with the architecture of long short-term memory and autoencoder as part of the technical diagnostic system of the service station, which allowed to predict equipment failures in a small number of anomaly precedents. The use of the neural network in diagnostic systems increases the reliability of predicting anomaly conditions by 9%.

Models of neural networks are implemented and tested. Model 2C8 with a training period of 12 months, 30 automatically selected independent variables, 4 hidden layers and 90 hidden neurons showed very good results and was selected as a reference model. This made it possible to predict the anomalous condition of the service station with a coefficient of determination of 0.965 based on the measurement of the surface temperature of complex thermal power facilities, which can be used as an indicator of the technical condition.

According to the results of research, it is established that models of neural networks with a training period of 4 months have relatively better characteristics, while the number of hidden layers and neurons is recommended to be determined experimentally.

Such approach to diagnostics of energy equipment can make energy industries more ecological, because concentrations of different pollutants in exhaust gases of thermal power facilities can use as information parameter of the process. So, continuous diagnostics on the bases of exhaust gases analysis can reduce the concentration of pollutants which throw out into the atmosphere.

Abstract. Complex economic, geological-technological state of coal mines and impact of the armed conflict factors (the breakdown of energy supply, objects of critical infrastructure, etc.) accelerated closure of coal mines by the method of "wet preservation" in particular. In most developed EU countries decommissioning of coal mines, which have great depth (up to 1,0-1,5 km) and areas of minefields, occurs according to the post-mining (PM) research and production complex, which is based on the scientific and technological activities regarding prevention of dangerous changes in the geological environment (GE) - subsidence of ground surface, lands flooding, emission of explosive and toxic gases as well as reduction of outflows of polluted water into the local river basins (RB) and the soil aquifer. Additionally, PM suggests some mining works turning into the hydraulic-filtration system of mine water retention at a depth of 250-350 m with a purpose of preventing pollution flow into the freshwater aquifers and river network, preserving regional aquitards, degassing of mountain surface. In general, the PM activities complex aims at maintaining the balance and protective potential of the GE as mineral and landscape basis of the biosphere, elimination of dangerous changes in ecological parameters of the hydrographical network. It is shown that new models of subsoil and water use, geological prospecting structure, scientific basis for permissible changes in GE and RB are required together with closure of "old" mining works (MW) and opening of new ones, improvement of the environment monitoring based on GIS technologies and Earth remote sensing.

1 Introduction

Market restructuring of the mining and industrial complex (MIC) of Ukraine has led to a significant increase of requirements to technic-economic and ecological-social parameters of the subsoil use. Critical acceleration (with the start of the armed conflict in 2014) of closure and liquidation of mines of Donbas mostly through "wet preservation" (auto-rehabilitation flooding) conditioned poor consideration of the object-territorial and regional changes in ecological parameters of the natural-technogenic geosystems (NTGS) "coal mining region - geological environment" under the current social-economic and geopolitical conditions [1-15].

From our point of view, during the period of restructuring of the leading coal mining sectors (CMS - Donbas, Lviv-Volyn coal basin, West Donbas, Dnipro brown coal basin) experience of EU countries (Great Britain, Germany, France, Poland, etc.) in creating a legal basis and substantiating the NGTS new state ecological safety parameters as a result of abnormal changes in ecological parameters of its leading element - technogenic-geological system (TGS) "mining complex - geological environment" has not been taken into consideration. It was mainly connected with uncontrolled flooding of most mines at insufficient consideration of the new ecological state of the geological environment (GE) as a result of restructuring its accumulated long-term changes within the boundaries of various NGTS of Donbas [1-6, 9-14, 16-21, 23-25, 35].

Under these circumstances, substantiation and implementation of post-mining principles and technologies relate to significant difficulties as a result of gaps in ecology legislation as well as a big complex of accumulated and newly created irreversible and dangerous changes in the ecological state of the subsoil.

Taking the above-mentioned into consideration, we can conclude that further functioning of the coal mining of Donbas on the controlled and non-controlled territories is possible based on accelerated post-mining activities implementation to the subsoil use on separate areas with sufficient power of mine pumping at further mining of coal fields.

2 Analysis of previous publications

The mining industry is dynamic, with some resources being mined for centuries until reserves are depleted or

* Corresponding author: anpilova@ukr.net

technical and market conditions change, as has been the case in the former communist countries after 1990.

In almost all known cases, the cessation of exploitation of mineral resources has led to a number of serious problems [36-49]. The problems are similar in all mining regions [44-60], and the research in this paper points out these facts.

Research experience of the Institute of Telecommunications and Global Information Space of the NAS of Ukraine shows that use of the GIS can facilitate a significant increase of reliability of estimates of the ecological-technogenic conditions of the NTGS "waste polygon-environmental constituents" on the condition of reduction of the geological environment defensive ability as a consequence of the mines and pits flooding [5, 19-34].

The main factors which define the ecological state of the Donbas coal mining sectors are:

- geomechanical and hydrogeofiltrational imbalance of the rock mass as a result of conducting mining works with the exemption of large volumes of mineral raw materials, formation of a significant amount of polluted underground water flow into the local river network (up to 800 million m^3 per year) and greenhouse gas (up to 6 bln m^3 per year), destruction of regional aquitards and development of non-watertight areas of technogenic fissuring;
- formation of mining and recycling waste;
- destruction of hydrogeological and hydrological conditions of the territory.

All the other factors (development of hazardous geological processes, pollution of the surface atmosphere, soil, loss of biodiversity, etc.) in most cases derive from these three factors [1-9, 17, 18].

3 The research results

The biggest ecological-technogenic, social-economical and technogenic threats to the population occur when coal mining enterprises closure is ecologically imbalanced due to the accelerated flooding of coal minings, level rise and pollution of local underground and surface sources of drinking and economic water supply beyond the claim mine concessions, additional deformation of the land surface, increasing upward migration of polluted mineralized water and explosive and toxic gases (methane, radon, hydrogen sulfide, etc.), which is connected with the depletion of regional waterproof (low permeable) layers [13, 17, 18, 25]. At that, soil pollution surface centres can get in the zone of active water exchange (industrial and domestic waste polygons), surface flow and groundwater, which can actively move to the rivers and expand the area of water ecological risk.

In practice, it can result in disabling surface and underground drinking water supply systems, flooding and destruction of housing and industrial objects and communication (including ecologically dangerous objects such as oil and gas pipelines, chemical enterprises, etc.), complicated conditions of agricultural activities. Uncontrolled development of these processes, which are mostly irreversible in the coal mining sectors of Ukraine, including the additional impact of the armed conflict complicating factors on the East, global climate change and so on can lead to an ecological disaster, consequences of which will be extremely long-term and regional (borderless).

At that, the analysis of long-term changes in the ecological parameters of various NGTS in Donbas allows concluding the leading impact under current conditions of the anthropization of the geological environment and the Siverskyi Donets river basin as a regional drain of the underground flow technogenic reformation.

The main factors of technogenic changes in ecological parameters of the GE and river basins (RB) in the Donbas region under the conditions of postmining are:

- chemical pollution of landscapes;
- significant lowering of the underground water level, undermining of surface water bodies (up to 600 cases with different level of the surface flow interception);
- highly mineralized aggressive mine water flow in the river system;
- accelerating exogenic geological processes (landslides, karst, flooding), development of the original ground subsidence and complicating the engineering-geological state of housing and industrial objects;
- decrease in engineering-seismic resistance of rock mass influenced by increase in mobility of rocks in the areas of their undermining by mining works, development of hydromechanical impulses, etc.;
- formation of a large amount of waste pits, which are also a source of water resources, ground and surface air pollution.

The most dynamic changes in ecological parameters of the geological environment and river basins in Donbas are connected with inflows of underground water into the coal minings, the overall flow level of which into the river network at a maximum development of mining works was 25,0 m^3/sec (1990). At a regional amount of natural water resources equal to about 12,0 m^3/sec, it indicated active drainage of surface water sources and hydraulic interconnection between mines [58-60]. At an average salinity of mine water equal to about 3,6 g/dm^3, it conditions the outwash of salts mainly into the Siverskyi Donets river basin at a level of 2,7 mln tons per year, which significantly activates pollution of the transboundary river flow in the Don (at the territory of Russian Federation) and Azov sea basin.

In the context of the armed conflict surface water objects, first of all, those of the Siverskyi Donets river basin, which is the major source of drinking and economic water supply (40-80% of local water consumption) have a significant threat of dangerous deterioration of the geological state.

Evaluation of the ecological state of the reserve sources of drinking and economic water supply of Donetsk and Luhansk regions population, on the controlled and non-controlled by the Ukrainian government territories, is extremely important, as it is conditioned by the active use of pollution vulnerable local dug wells, boreholes and reservoirs by the local population beyond the central water supply system.

The authors created an indicative scheme of carrying out express research in the given region, which allowed evaluating the most vulnerable section critical for the health and ecological safety.

An important component is defining the role of emerging technologies, use of contact, remote methods of monitoring and geoinformation technologies (GIS) in particular.

Based on the geodata integrated into GIS, authors built models of surface water pollution dynamics in the Siverskyi Donets river basin.

To build models of pollution space distribution and evaluation of surface water quality authors used geostatic methods that allowed receiving interpolation area of pollution level values and building relevant maps of surface water quality change probability in the whole basin and the territory overall.

Activation of technogenic changes in, first of all, the surface flow of Donbas, is influenced by undermining of 129 rivers and beams and 26 reservoirs (> 683 cases) caused by mining works as well as by continuous subsidence of the original surface on the territory up to 8000 sq.km in the area of impact of which there are up to 1000 different industrial and potentially dangerous objects (Fig. 1) [1, 13, 25].

A significant complication of the mines closure process creates up to 250 earlier flooded mines, hydraulically connected with the active ones. According to the current evaluation, total mining works exceed 2,3 km^3 and contain up to 1,6 km^3 of water which can significantly accelerate regional activation of flooding of cities and villages territories, migration of pollution into the surface and underground intakes and the river network, as well as increase threat of emergency water breakthrough into the active.

Additional above-mentioned evaluations allow concluding that transformation of water-ecological parameters of natural-technogenic geosystems (NTGS) “mining complex - underground and surface hydrosphere” in the context of current auto rehabilitation flooding of mines in Donbas has considerable complexity and uncertainty during the implementation of post-mining activities. It is mostly conditioned by the fact that areas of the underground water level rise 5-10 times and more exceed areas of mining works, thus forming dynamic reformation of levels and chemical composition of underground water and its flow into the hydrographical network.

In our view, under the current conditions of social-economical and ecological-technogenic restructuring of subsoil use in Donbas, the biggest water-ecological threats to health and safety of a large number of people in the region (more than 50%) occur when mining enterprises are closed without a sufficient complex of protective and ecological-stabilizing activities. Taking into consideration a spatial-temporal structure of factors of the changes in ecological parameters of GE and the surface flow of Donbas, we have substantiated a scale of ecological impact of the coal industry zone post-mining initial phase on the state of life-supporting components of the environment (lithosphere, hydrosphere, etc.).

The authors’ evaluations showed that in the biggest by area and depth of mining works region of Donbas ecologically critical consequences of the auto rehabilitation flooding of mines (so-called “wet preservation”) are connected with the absence of a pumping-hydraulic system which should keep the underground water level on the ecologically optimal depth lower than the regionally permeable crust of weathering coal rocks (from the experience of the EU countries - 250-350 m.). The given approach excludes active lateral spreading of polluted and mineralized mine water and its flow into the overlying freshwater aquifers and surface streams.

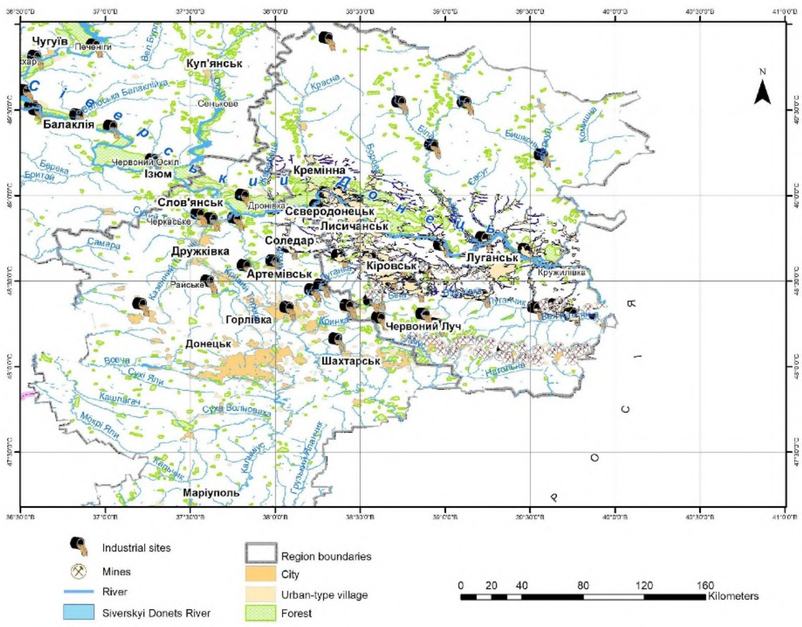

Fig. 1. Map of technogenic pressure on the Siverskyi Donets River Basin.

The experience shows that at that, underground water level rise beyond the claim mine concession, additional surface subsidence, increasing migration of polluted mineralized water to underground and surface sources of water supply and explosive and toxic gases to housing and industrial buildings also occur in the most MW, which is mostly connected with tectonic and technogenic depletion of waterproof layers. The Fig. 2 shows the fundamental scheme of formation of underground and surface water flows interaction during the coal mine flooding in Donbas.

Taking into consideration the above-mentioned characteristics of interaction between the underground and surface water flows during the flooding of a coal mine in Donbas we have developed the "Scheme of the technogenic-geological system "mining complex - geological environment" transition into the post-mining phase", is presented in Fig. 3.

The above-mentioned values show that disturbance of the balanced geomechanical state of the subsoil, level and hydrochemical mode of underground and surface water and deformation of the earth's surface in the context of auto rehabilitation flooding of mines ("wet preservation") are the main factors of development of potentially water-ecological threats and risks of emergencies of water-ecological nature.

Fig. 2. Fundamental scheme of formation of underground and surface water flows interaction during the coal mine flooding in Donbas.

In general, results of the analysis of changes in the water-ecological state of developed ("old") mining regions of Donbas considering critical technical-economical parameters of the natural resource potential achieved by them before the transition into the post-mining phase allow concluding possibility of partial realisation od correspondent activities on improvement of water-ecological safety of vital activities.

Mainly it is connected with the irreversible disturbance of balanced natural interaction between the underground and surface components of the Donbas region hydrosphere as a result of exemption of large volumes of the coal mass followed by ruining regional aquitards and river valleys, subsidence of large areas of the earth's surface, geochemical pollution of surface and underground water-collecting landscapes, the collapse of host and casing rocks.

In that regard, in our opinion comparison of renewal levels of geological environment ecological-protecting functions (mostly ground and rocks of the aeration area) and surface hydrosphere (sediment) of the Chernobyl Exclusion Zone and the zone of the flooding of Donbas Central region mines are illustrative, is presented in Table 1.

Table 1. Comparison of changes in the ecological status of the geological medium of the Exclusion zones and the unconditional (obligatory) resettlement of the Chornobyl NPP and the impact area of the massive closure of mines in the Donbas (Influences levels: red – critical, yellow – dangerous, green – background).

Types of changes in the ecological condition of the geological medium	Technogenic influence factors	
	Chornobyl NPP emergency area	**The area of impact of a large-scale closure of the Donbas mines**
Landscape and geochemical pollution	Auto-rehabilitating cleanup (up to 90% by 2035)	Irreversible changes
Lithospheric - equilibrium	No changes	Destructive changes
Hydrological	Short-term radionuclide pollution	Sustainable pollution
Hydrogeological	Low concentrations of radionuclides	Pollution and depletion of groundwater resources
Gas-geochemical	Short-term contamination of the atmosphere with radionuclides	Increasing pollution of surface air pollution
Engineering-geological	Almost no changes in engineering-geological conditions	Destructive changes
Seismic-engineering-geological	Relatively stable condition	Reduction of engineering and geological stability

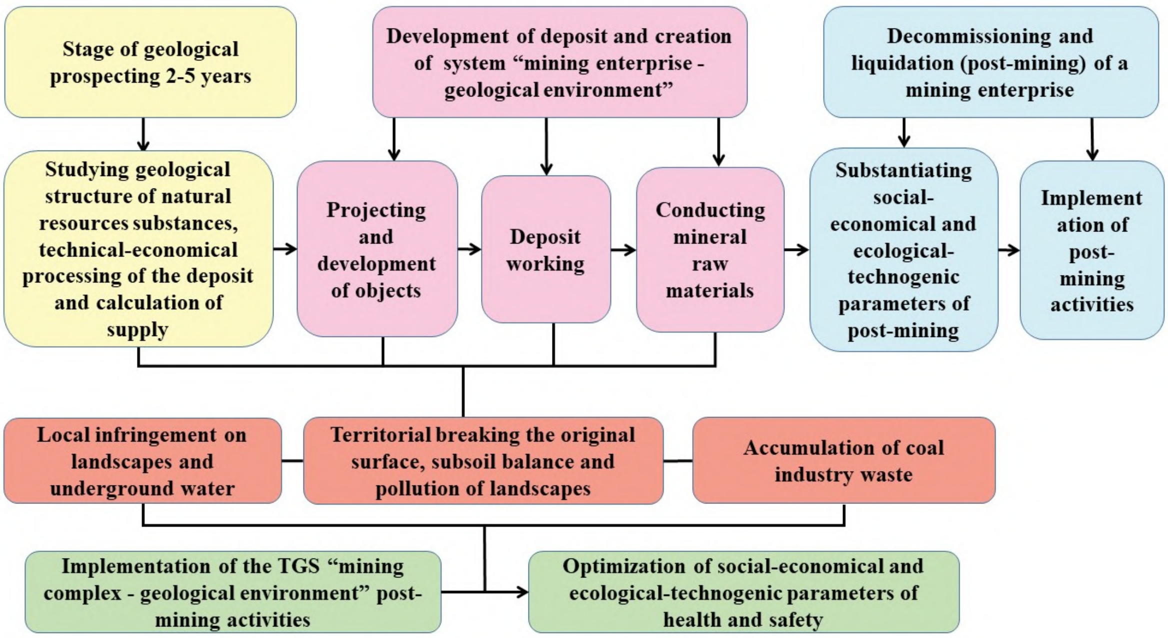

Fig. 3. Structural scheme of formation of the post-mining methodical base in the context of ecologically stable development of mineral raw materials deposits.

Based on the data given in table 1 ecological state of the geological environment as a part of an NTGS is a crucial parameter of the natural resource potential renewal and formation of water-ecological factors of health and safety.

4 Conclusions

Based on the above-given evaluations a complex of ecological-technogenic and social-economical post-mining activities in the most MS in Donbas can be partial, taking into consideration irreversibility of most changes in ecological parameters of a geological environment and surface hydrosphere, which have occurred or are at a stage of active development. At that, a large number of ecological functions of a geological environment (landscape-chemical, water-ecological, engineering-geological, etc.) are lost in almost all developed CMS at the post-mining stage due to complex violations of the subsoil balance during exemption of large volumes of copper rock raw materials and creation of “lack of mass” in the upper zone of the lithosphere.

Thus, the main task of the post-mining separate activities implementation focused on the improvement of health and safety of the local population in the mining sectors of Donbas can be the following:

- improvement of forecasting the changes in main life-supporting components of the environment (ground, hydrosphere, subsoil, etc.);
- proactive development of a compensatory model of a stable social-economical and ecological-technogenic development of mining sectors in Donbas taking into account the restructuring mining complexes experience in the EU countries (Germany, Great Britain, etc.);
- improvement of the monitoring structure based on the broadening the complex of evaluating parameters, implementation om mathematical models of TGS in the mining sectors, use of the GIS and ERS technologies (interferometry, spectrometry and so on);
- scientific basis for permissible changes in the ecological parameters of the environment components and long-term health and safety;
- provision of long-term exploitation of the critical infrastructure objects (energy, water and heating supply complexes, transport network, etc.);
- increase in consumption of fresh underground water resources as a protected from technogenic pollution resource of drinking and economic water supply;
- definition of farmland sectors which are geochemically safe for receiving agricultural commodities.

In general, the stage of creating basis and developing the post-mining policy in the CMS in Donbas for the economics and a large number of people is a strategic scientific-technological and social-economical task, taking into account the leading role of a coal-raw component in contributing to the GDP and providing resource and energy safety of the country.

Abstract. The zone of infiltration of the drilling fluid filtrate into the reservoir rock creates significant difficulties for the study by logging methods and during further testing of the formation. Due to the penetration of filtrate, significant contamination of the near-wellbore zone occurs. The porosity and filtration characteristics of reservoir rocks are changing. There is a possibility of blockage by filtrate in the invaded zone of oil or gas flow from the formation to the well. As a result of the studies carried out using well logging data, it was found that the presence and distribution of a mud cake on the borehole wall opposite the reservoir is an important factor influencing the process of filtration of the drilling fluid into the layers. On the examples of the Yablunivske oil and gas and Kolomatske gas fields of the Dnieper-Donets basin, it is shown that the absence of a mud cake on the borehole walls leads to the formation of maximum, anomalous zones of filtrate invasion. The determining of the diameter of the invaded zone was carried out according to the data of electrical logging methods. In addition, the diameter of the invaded zone was calculated as a solution direct task equation for the case of direct filtration without blocking by the mud cake. Comparison of the results of determining the diameter of the invaded zone by two methods made it possible to draw certain conclusions. An important conclusion is that even partial absence of mud cake on the reservoir wall in the well leads to horizontal and vertical filtration of the drilling fluid from the well into the formation. As a result, the invaded zone may be so deep, that the gas flow rate is absent even at high values of porosity, permeability and gas saturation.

1 Introduction

The process of drilling an oil and gas well inevitably causes the environmental contamination. Including geological. In addition to creating a hole in the wellbore in the permeable layers, a zone of invasion of the drilling fluid filtrate is formed. This filtrate is actually an aqueous solution of inorganic and organic compounds, significantly changing the geological environment around the well. The changes concern the porosity and permeability of reservoir rocks; there is a swelling of clay minerals, the well space is clogged with solid particles and colloids.

2 Theory and Methods

The main methods that allow to study the well outer space during and after drilling –the well logging. Actually, only with the help of the results of geophysical research it is possible to really estimate the size (diameter) of the invasion zone of infiltration of the filtrate into the porous layer. The principles of estimating the size of the filtrate invasion zone and its electrical characteristics were developed in the 50s of the last century [1]. Along with the development of sounding technology for electric logging systems of different sizes (BKZ), the interpretation of the logging data was proposed [1-3]. The wellbore space was considered as a 2-or 3-z medium. In the presence of filtrate penetration, it was considered that this invasion (penetration) zone (ZP) has different electrical characteristics than the formation and the well itself. The relative diameter of the invasion (penetration)zone Dzp/Cal was determined using the so-called 3-layer palettes BKZ. The most famous scientists, whose work was the basis for the interpretation of BKZ data, include the work of H.G. Doll, V.M. Dakhnov, S.G. Komarov, L.M. Alpin. Currently, the determination of the diameter of the invasion zone and its specific electrical resistivity is performed based on the results of studies of wells with multi-probe gradient probes, lateral logging, induction logging [4-7]. Thanks to the data of electrologging, researchers have the opportunity to assess and analyze the degree of filtration and the processes that occur during the formation of the invasion zone [8-10]. Here, geophysical methods are used as a tool to determine the parameters of the filtrate invasion zone in field research and interpretation of reservoir test results, features of primary reservoir opening, planning of optimal methods and perforation technologies [11-12].

* Corresponding author: karpenko.geol@gmail.com

Calculations of the size of the invasion zone by solving the direct filtration task [13-18] indicate a wide range of approaches to take into account various factors that affect filtration processes in the gradient space around the well. Therefore, considerable attention should be paid to statistical modeling of the invasion zone based on the use of a priori information, which can be obtained from geophysical and other studies in drilled wells [19].

The total volume of permeable liquid leachate depends on the duration of time from the start of filtration, repression of pressure on the reservoir, the viscosity of the filtrate and formation fluid (and other rheological properties), the permeability of the reservoir [20, 21] and the thickness of the mud cake [18, 22, 23].

The volume of filtrate that penetrated into the formation can be divided into two components. The first stage of penetration is the rapid absorption of the filtrate by the formation (instantaneous filtration). The second stage is the filtration of the washing liquid through the mud cake. However, even the inhibition of filtration into the formation by increasing the mud cake does not always contribute to the formation of small penetration zones. There are many examples of this, when under all the positive conditions regarding the reservoir characteristics of the formations, the presence of mud cake, the tests did not receive significant inflows of fluids into the wells [17, 24-26]. In addition, the technological parameters of drilling significantly influence the test result. According to the data [15-16], many wells drilled in Ukraine did not produce during development. These include the well № 100 - Kiltsivska Square, № 1 - Bitlyanska in the Dnieper-Donets Basin and several wells in the western region with very low reservoir pressures, namely: № 1 - Hutsulivska, № 3 - Kolomyia, № 6 - St. Bohorodchanska. All of them were drilled with excessive excess density of the drilling mud, respectively, huge invasion zones were formed. Only after changes in the drilling regulations by reducing the density of the flushing fluid from the standard used 1.20 to 1.10-1.20 g/cm^3 was obtained a conditional gas inflow.

Static and dynamic studies of the filtration properties of the washing liquid are used to estimate the filtration rates. To date, there is no universal model for calculating the parameters of the invasion zone, including its diameter.

If we do not take into account the influence of mud cake, then the first approximation, the depth of the penetration zone can be calculated by the following equation [16]:

$$L = \frac{\Delta p \cdot \sqrt{K}}{a \cdot \tau_0}, \qquad (1)$$

where L is the radius of the invasion zone, m; Δp - real repression of pressure on the formation, Pa; K - permeability coefficient of the rock, m^2 [20, 21]; a–is the coefficient that can be taken [16] equal to (155-180) $\cdot$ 10^{-4}; τ_0 –maximum / limit shear stress, Pa.

Thus, under normal conditions (Δp = 2 · 106 Pa; K = 10 · 10-15 m^2; a = 160 · 10-4; τ_0= 10 Pa), the calculated value of penetration of the filtrate into the formation (in the absence of mud cake) is equal to 1.25 m. This is a fairly significant value, which may already be the cause (or explanation) of the absence of inflow into the well of formation fluid or gas during testing.

Consider real examples of the absence of positive test results in comparison with the parameters of the layers and the invasion zone.

Well 14-Yablunivska (Fig.1). Testing of productive strata determined by the well-logging data was carried out according to the classical bottom-up scheme. In the interval of perforation by the corpus perforator PKOT-73 after 3 times aeration of salt water the inflow in the well was not obtained. Although the reservoir parameters of the reservoir (interval 5070-5071.6 m) are much higher than the limit: porosity 10%, permeability coefficient 41.2 mD (by the well-logging), gas saturation – 83%. The authors of the first report (1984) on the petroleum reserves calculation of Yablunivske field note that chalk was used as a weight addition during drilling; as a result, a large invasion zone with significantly deteriorated filtration properties was probably formed. This is the main explanation for the absence of fluid inflow from this reservoir. According to our calculations, the relative diameter Dzp/Cal here is 18.5, and the absolute value of Dzp = 3.7 m.

Layers were also tested above the section in this well. In the range of 4921.6-5049.0 m (perforation by PKS-80) at the first lowering of the water level received a small inflow of gas with a flow rate of 1.5 thousand m^3/d. Only after 3 times of aeration the formation began to work with a gas flow rate of 49.2 thousand m^3/d. on an 8-mm fitting. The weighted average parameters of reservoirs in the test interval: total layer thickness 48.7 m, porosity 11%, permeability coefficient 132.6 mD, gas saturation 84%. According to our calculations, the relative diameter Dzp/Cal here is 7.9, and the absolute value of Dzp = 1.5 m.

In the third interval 4876.8-4911.8 of perforation by the corpus perforator PKS-89 after replacement of salt water with fresh water a significant inflow of gas was immediately obtained - 284.8 thousand m^3/d. on an 8-mm fitting. The reservoir properties of the formations are as follows: total layer thickness 10.5 m, porosity 14.7%, permeability coefficient 211 mD, gas saturation 85%. The relative diameter Dzp/Cal here is equal to 5.1, and the absolute value of Dzp = 1.1 m. The given example of test results of terrigenous section layers of the Tournaisian stage in one well of Yablunivske oil and gas field testifies to the importance of taking into account not only the main reservoir parameters of formations (porosity, effective thickness and gas saturation), but also the permeability coefficient (penetration) [27, 28]. Inflow call technologies should be adjusted to take into account the size of the filtrate invasion zone with appropriate measures, including re-perforation.

In Fig. 1 shows the curve of the calculated values of the invasion zone depth (Lzp) according to the model (1) [16] of filtration into the formation in the case the absence of mud cake. The presence of mud cake makes significant adjustments to the size of the invasion zone.

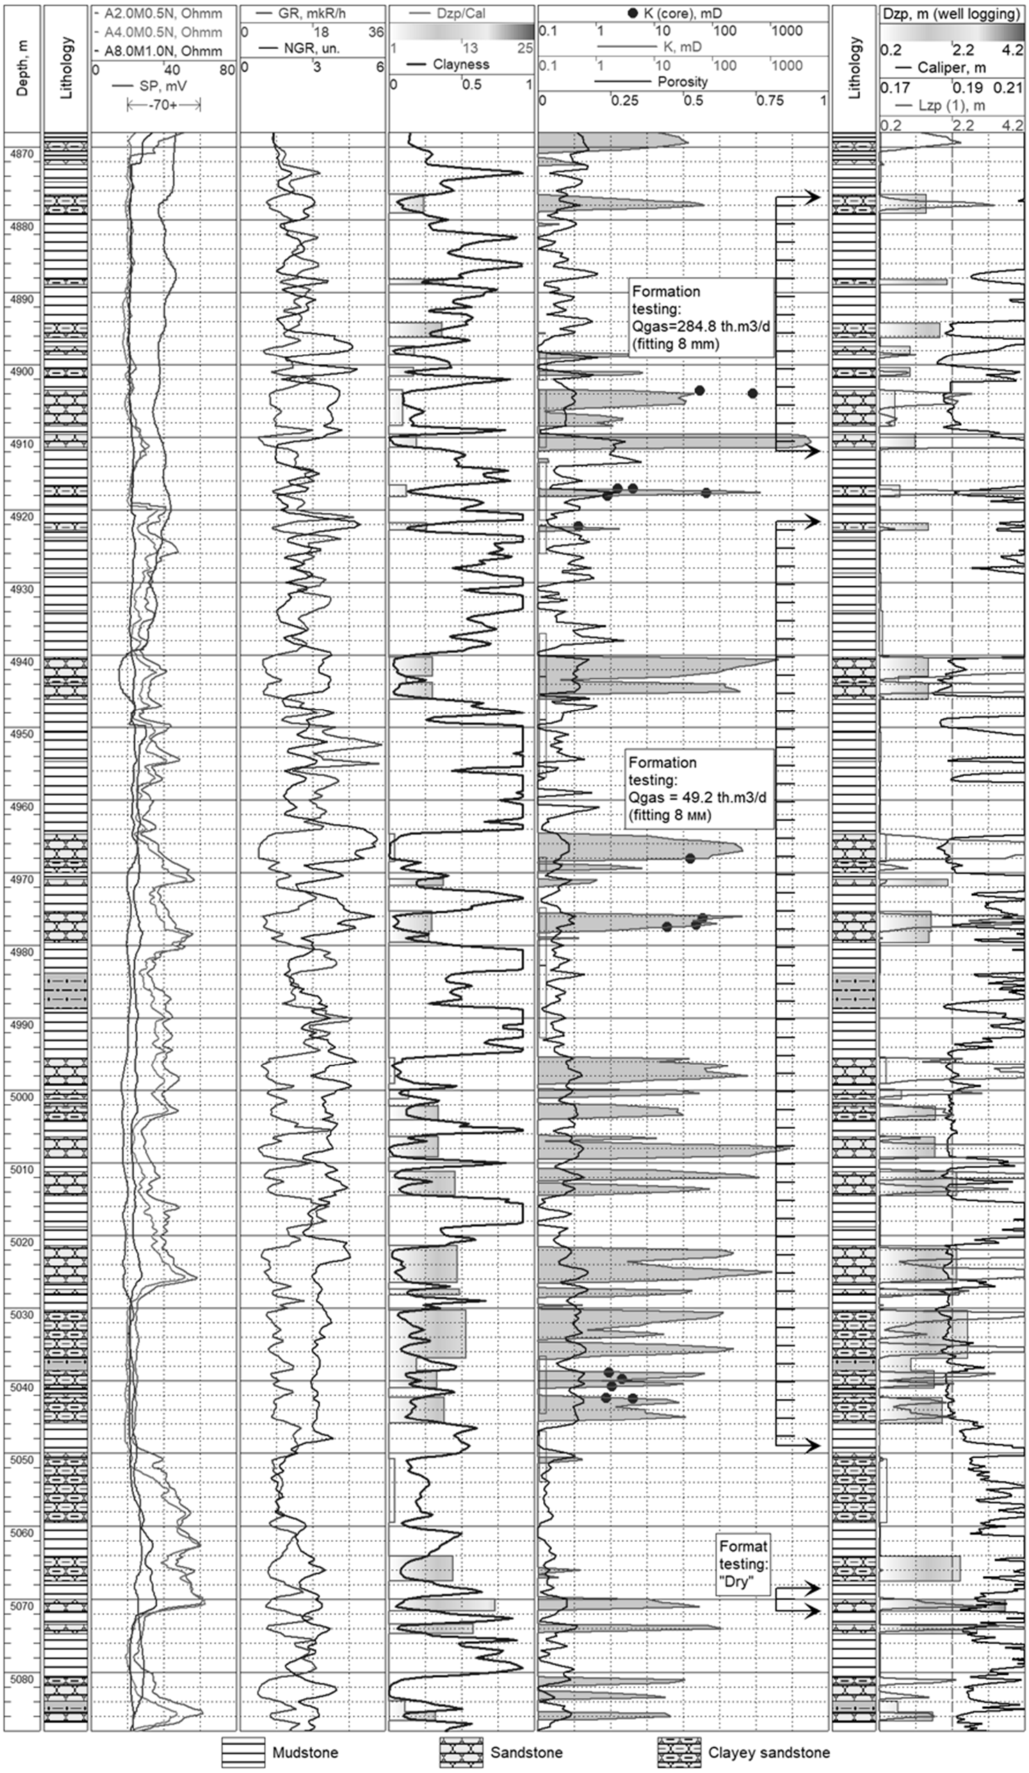

Fig. 1. Section of 14-Yablunivska well with the given test results and calculated values of the relative invasion zone according to well-logging data interpretation.

The tendency is clearly visible: where is the mud cake (the diameter of the well is less than the diameter of the bit), the (in the main) the actual value of the diameter of the invasion zone is smaller than calculated without taking into account the effect of reducing the filtration through the mud cake. In the lower part of the section (Fig. 1), where the largest values of Dzp are observed, there is no mud cake at all. Due to the possible structural inhomogeneity of the rocks of the lower part of the Tournaisian stage, zones with increasing diameter were formed during drilling, in the absence of mud cake formation. As a result, there are large areas of filtrate penetration and negative results during the testing of formations (Fig. 2).

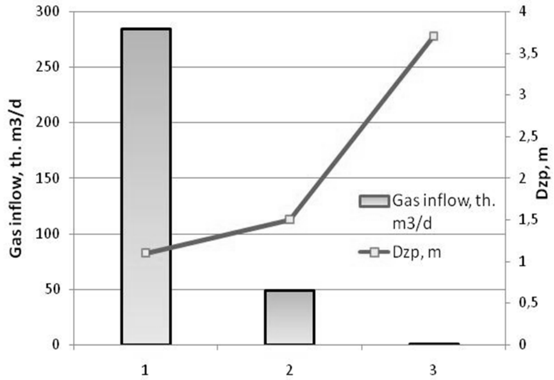

Fig.2. The ratio of the diameter of the invasion zone (according to well-logging data interpretation) and the obtained gas flow rate opposite the reservoirs of 14-Yablunivska well.

Similar negative test results due to the presence of a large zone of filtrate penetration in the sections of the wells, where there are gas-saturated reservoirs, were obtained in the significant number of Dnieper-Donets basin oil and gas fields. In Fig.3 shows a tablet of log diagrams with the results of interpretation and test data of layers and perforation intervals of 31-Kolomatska well. It should be noted that the productive terrigenous strata of the Serpukhovian stage at the Kolomatske gas condensate field lie at considerable depths, more than 4500 m. 31-Kolomatska well show that a number of productive objects with porosity values higher than the critical 6.5 - 10.5% are distinguished in the section. Gas saturation coefficient - in the range of 61 - 78%.

During the testing of formations in the section interval 5486 - 5512 m inflow was not received. Perforation was performed using modern equipment OWEN 3 3/8 "with a frequency of 18 holes / m. According to the well-logging data, all layers of sandstone in this interval are productive (Fig. 3). Above in section according to the results of a joint test of two perforated intervals 5464 - 5475 m and 5440-5452 m received a conditional gas flow of 191.4 thousand m^3/d on a 7-mm fitting. The equipment and conditions of perforation here were similar.

Pays attention to the fact that in the lower test interval 5486 - 5512 m with negative results on the caliper curve there is almost no mud cake; the diameter of the well is larger than the diameter of the bit opposite the reservoirs. At the same time, in front of sandstones in the two upper perforation intervals 5464 - 5475 m and 5440-5452 m there is a mud cake everywhere (see curve Caliper in Fig. 3). Calculations of the values of the relative diameter of the invasion zone Dzp/Cal according to the electrical methods of well-logging using the GeoPoisk system [29] showed the following. In the test interval 5486 - 5512 m, the values of Dzp/Cal in the reservoirs vary from 6.4 to 11.1.

In the upper intervals, where a significant gas flow is obtained, the values of Dzp/Cal are generally at a minimum level of 2.0. Such values are observed in front of reservoir layers with porosity values greater than the limit values. Only in the range of 5470.5-5474.6 in the calculations obtained the value of the relative diameter of the invasion zone of 6.2. We calculated the point values depth of the invasion zone of the filtrate *L* by formula (1) [16]. These results correspond to the possible values of filter penetration in the absence of mud cake. In the lower interval in the negative test results in the actual absence of mud cake, the calculated values of the relative diameter Dzp/Cal according to electrologging correlate well with the curve *L (Lzp)*. That is, the fact of the presence of a large zone of filtrate penetration led to the absence of gas inflow to the well according to the test results (int. 5486 - 5512 m).

To verify the statement about the identity of reservoir rocks by their capacitive and productive properties in the intervals with different test results, statistical analysis was performed using Student's t-test. For this purpose, two multidimensional sample sets with the conditional names "gas" and "dry" were formed - according to the test results. Selection of parameter values was performed with a step of 0.5 m from log diagrams.

Table.1 gives a clear picture of the statistical characteristics (mean and standard deviation) of the main geophysical parameters and coefficients of clayness, porosity and gas saturation of the two objects (samples).

According to the table data, the limit value of the Student's t-test is equal to 1.99 by the value of the confidence interval $\alpha = 0.05$. As you can see, only the mean (average) values of the diameter of the well, the intervals of the section have significant differences. Here, the value of the t-test 4.7 is significantly greater than the limit value of 1.99 (see Table 1) That is, the absence of mud cake (increasing the diameter on the Caliper curve) led to the formation of a large invasion zone in the sandstone interval with negative test results. Thus, there is reason to believe that the results of the preliminary conclusion about the presence of a gas-saturated reservoir within the test interval 5486 - 5512 m are statistically confirmed. And the test results in this interval should be considered unproven.

3 Conclusions

The process of drilling mud penetration into the reservoirs and the formation of the invasion zone can be divided into three main stages. In the first stage, when drilling near the bottom of the well in the area of the most active circulation of the flushing fluid, there is an area of high pressure with a large pressure drop not only in the radial direction, but also along the axis of the well. In the second stage, an important factor in the formation of the invasion zone is the formation of a mud cake on the wall of the well, which significantly impedes the water exchange processes between the well and the layers [30]. In the initial moments of time there is a squeezing of formation water and oil / gas phase from the bottom hole, which has a spatial character. In the third stage, after the drilling tool leaves the reservoir, the displacement process is mainly due to the excess of the constant hydrodynamic pressure in the well above the reservoir pressure and is mainly radial [30].

Our research using the methods of mathematical statistics proved that for terrigenous reservoir rocks with a granular type of porosity on the examples of several oil and gas condensate and gas condensate fields the following was established.

1. Negative test results of formations (with the recommended oil and gas potential according to the well-logging data) in the perforation intervals are caused by the presence of anomalous zones of penetration of the flushing fluid filtrate [24, 31]. Among other factors of different nature, the depth of the invasion (penetration) zone (Dzp) is largely controlled by the presence and size of the mud cake. The presence of a mud cake leads to "containment" or "inhibition" of the filtration of the liquid into the formation, resulting in the formation of small invasion zones. It is recommended to compare the calculated values of the penetration depth of the filtrate *L (Lzp)* in the absence of mud cake (1) with the values of the diameter of the penetration zone Dzp according to the electrical methods of well-logging. Similar in size, the large areas of the filtrate invasion by two calculations are evidence of a problematic situation and a high probability of no fluid inflow from the formation during the test. The use of calculations in two ways significantly increases the reliability of the conclusions about the flow of the invasion zone on the test results.

2. It is proved that the presence of a mud cake along the entire thickness of the productive layer significantly affects the formation of small zones of penetration of the filtrate and contributes to obtaining reliable test results within the perforation interval. If the mud cake is only partially formed within the formation crossing by the well, then there is a high probability that the filtrate penetration can occur not only in the radial but also in the vertical directions in the formation, which can cause large diameters of the invasion zone Dzp.

Abstract. The paper presents the comparative analysis of the amount of waste generated in Ukraine and European countries (except for radioactive waste) based on the official EU and Ukrainian statistical data. The data on waste generation are compiled according to the following classification: by economic activity and household, waste category, grades of hazard, and regions. In Ukraine, 352.3 million tons of waste was generated in 2018. By 2018, almost 13 billion tons of waste had been accumulated at the managed dump-sites, including about 12 million tons of hazardous and over 200 million tons of household waste. In the European Union, 2.6 billion tons of waste was generated in 2018. Over 70% of it was generated by 10 countries: Germany, France, England, Poland, Romania, Italy, Sweden, the Netherlands, Spain and Finland. By economic activity, the largest amounts of waste in Ukraine are generated by the mineral extraction and processing industry, the smallest – from water treatment and construction. In the EU countries, these values are somewhat different. For example, in Germany and France, the largest amounts of waste are generated from construction and manufacturing, the smallest – from agriculture, forestry and fishery. By waste category, the waste generated both in the EU countries and in Ukraine is mineral and solid waste. In Ukraine, the largest amounts of waste are produced and accumulated in the Dnipropetrovsk, Donetsk and Zaporizhzhia regions which accommodate large enterprises for extraction and mineral processing of iron and manganese ores, titanium-zirconium placers, coal, dolomite, and metallurgical limestone, as well as metallurgical and ferroalloy plants.

1 Introduction

Rapid global economic growth at the end of the last millennium led to excessive use of non-renewable natural resources and increase of human impact on the environment. The amount of generated waste became one of the challenges facing humanity in the nearest future.

In accordance with the national waste management programmes, the European Union and Ukraine make inventories of the waste generated both by economic sectors and households. The waste inventories reflect the socio-economic differences and different approaches to treatment and identification of waste types. The list of waste used in Ukraine does not fully correspond to that in EU. In 2014–2017, Ukraine took initial important steps to change the situation through commitment of compliance with the EU Directives as a part of the Association Agreement with the EU and adopting the National Waste Management Strategy until 2030.

Waste statistics play an important role in understanding and monitoring respective changes in the production/consumption processes towards more sustainable solutions.

The data used in the article were taken from the Eurostat and Ukrstat databases for 2018.

The amount of waste generation in different countries varies depending on the economic activity and society's production and consumption patterns. The largest amount of waste is generated in countries with developed mining and metallurgical industries. At the same time some countries with high level of household consumption demonstrate significant generation of household and construction/deconstruction waste. Although the three biggest economies – Germany, the United Kingdom and France – have the highest generation of waste in absolute figures, no direct link between economic production and waste generation is observed for all EU countries. For example, in smaller economies like Bulgarian and Romanian, the waste generation in mining and metallurgical industries is amongst the highest.

Limited natural resources, environmental impact of rapidly growing amounts of waste require urgent measures aimed at waste reduction.

Waste management is a key environmental concern both in Europe and Ukraine. The situation in Ukraine has already proven to be critical in many cities and regions due to a lack of proper waste management infrastructure

* Corresponding author: gvg131619@gmail.com

and adequate government policy, business approach and public response.

2 Results and discussion

According to the State Statistics Service of Ukraine (Ukrstat), over 300 million tons of waste have been generated annually from 2014 to 2018, including 0.6 - 0.7 million tons of hazardous waste and over 10-11 million tons of household waste. By 2018, almost 13 billion tons of waste have been accumulated at the managed dump-sites in Ukraine, including about 12 million tons of hazardous and over 200 million tons of household waste (the data for the temporarily occupied Crimea and some territories of Donetsk and Luhansk regions are not included) (Table 1) [1].

Table 1. Waste generation and accumulation at the managed dump-sites in Ukraine, mln. tons.

Year	Total waste generation	Hazardous waste	Household waste	Total waste accumulation at managed dump-sites	Hazardous waste	Household waste
2014	354.803	0.7	10.748	12115.241	11.951	166.112
2015	312.267	0.6	11.492	12281.353	11.996	170.306
2016	295.870	0.6	11.563	12451.659	12.102	174.514
2017	366.054	0.605	11.271	12442.169	12.198	201.145
2018	352.334	0.627	10.000	12972.428	12.217	227.435

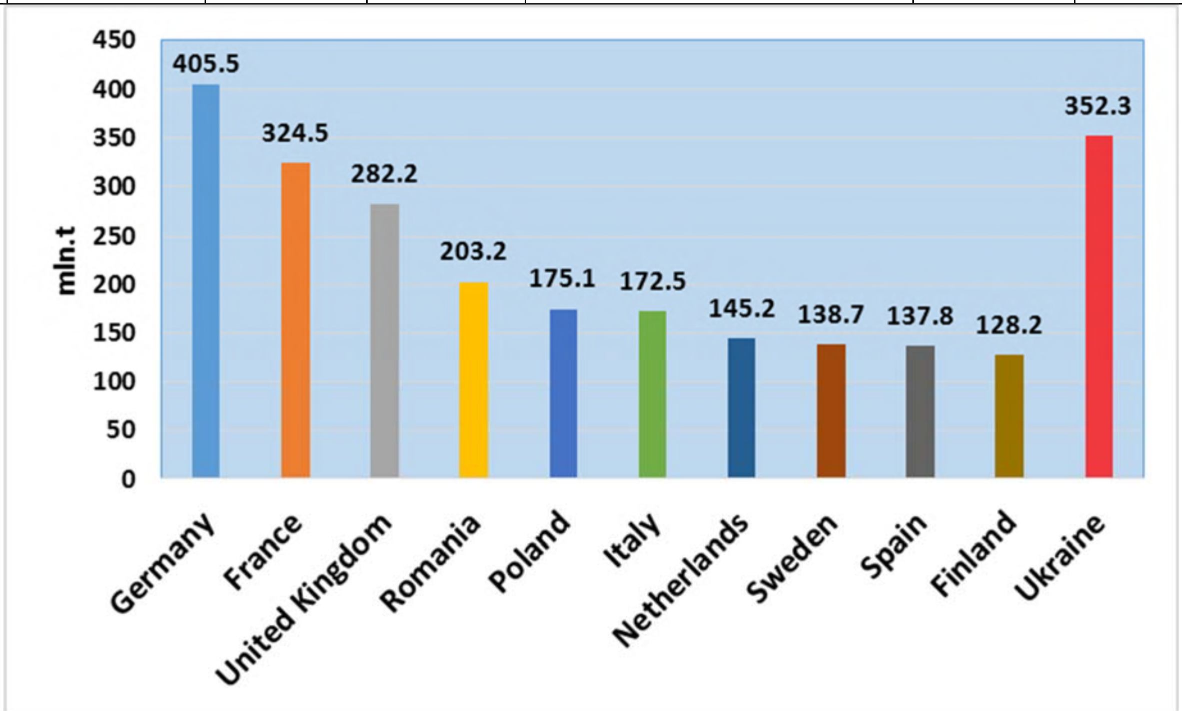

Fig. 1. Waste generated by some EU countries and Ukraine.

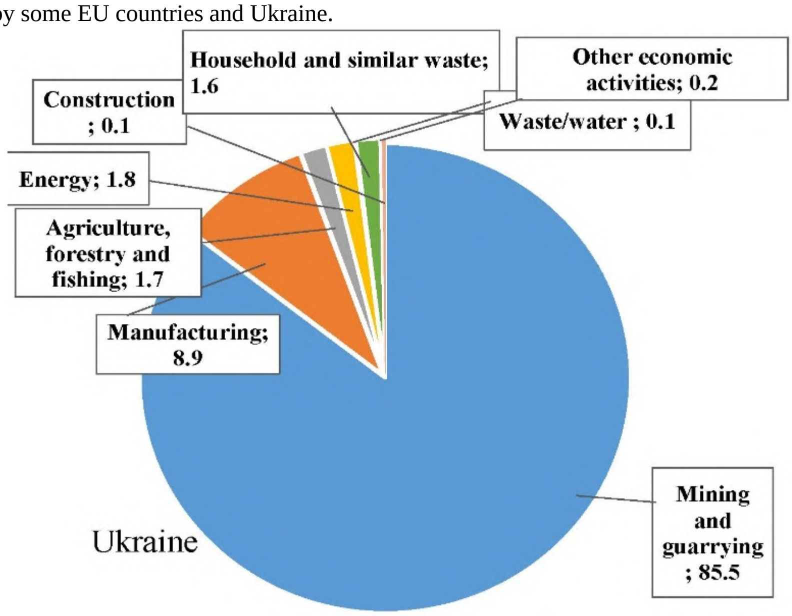

Fig. 2. Waste generation by activity in Ukraine, mln. tons.

According to Eurostat data, 2.6 billion tons of waste was generated in the EU (EC-28) in 2018 (Fig. 1). More than 70% of it was generated by 10 countries: Germany, France, United Kingdom, Romania, Poland, Italy, the Netherlands, Sweden, Spain, and Finland [2].

As can be seen in the chart, the amount of waste generated by some European countries in 2018 in million tons was as follows: Germany - over 400, France - over 300, UK – about 280, Romania - about 200, Poland and Italy - more than 170, Netherlands, Spain and Sweden - about 140, Finland - more than 120. In Ukraine, the amount of waste generated was over 350, which is less than in Germany and more than in France and the United Kingdom.

According to Eurostat data, in 2018 the following amounts of waste (mln. tons) were generated by each of the following European countries: Turkey – 90, Greece, Belgium, Austria and Serbia – from 40 to 70, Czechia, Estonia and Denmark - over 20, Hungary, Ireland, Portugal – from 14 to 18, Luxembourg, Slovakia, Norway – from 12 to 14. From 1 to 6 million tons were generated by other EU countries.

The State Statistics Service of Ukraine keeps records of waste generation and accumulation at the managed dump-sites in accordance with the National Waste Classifier. Waste is classified according to different parameters (by economic activity, waste categories, hazard classes, required disposal operations, and households). The same inventory strategy is used in the European Union.

Based on the State Statistics Service data [3], the chart in Fig. 2 presents waste generation by economic activity in Ukraine.

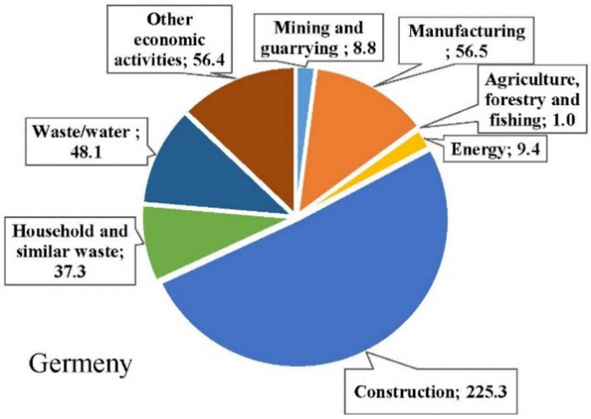

Fig. 3. Waste generation by economic activity in Germany, mln. tons.

The largest volumes of waste in Ukraine (million tons) are generated by quarrying and mining – 301.4 (74.3%), and manufacturing – 31.5 (17.5%), the later includes metallurgical and chemical enterprises, food industry etc. Household waste amounts to 5.5 million tons (1.1%). For comparison, in Germany and France, the largest volumes of waste are generated by construction industry – 225.3 million tons (55.6%) and 240.2 million tons (70.2%), and the manufacturing industry – 56.5 million tons (13.9%) and 22.4 million tons (6.6%) respectively. The household garbage volume is 37.3 million tons (9.2%) in Germany and 29.7 million tons (8.7%) in France (Figs. 3, 4) [2].

According to the State Statistics Service of Ukraine [1], the main sources of waste generation and accumulation in Ukraine are the following economic sectors (Table 2). Thus, the largest amount of waste in Ukraine is generated by quarrying and mining operations – over 300 million tons. It makes on average 74.3% of the total waste. At that, 80% is the waste from metal ore extraction (iron, manganese, titanium-zirconium). According to the National Waste Classifier, metal ore mining and quarrying waste in Ukraine include slurry and tailings, waste from pelletes and flux production (dust, powder, etc.), red mug from alumina production, and non-ferrous metal ore processing waste.

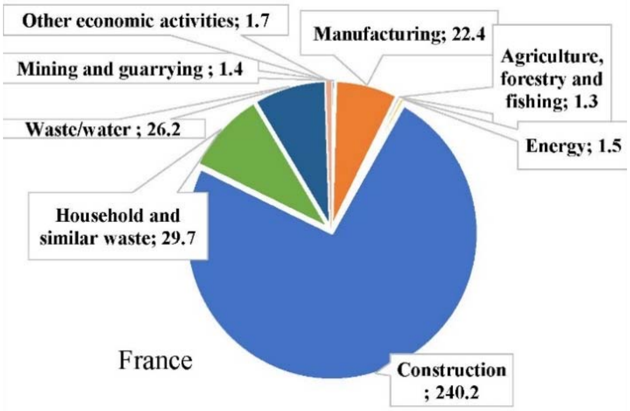

Fig. 4. Waste generation by economic activity in Germany, mln. tons.

Households	*6.3*	*6.0*	*6.3*	*5.9*	*5.5*

The group of waste from hard coal, lignin and peat mining includes substandard coal, slurry and tailings from concentrating mills. Other group of waste generated by Ukrainian enterprises comprises waste from mining of granite, limestone, chalk, dolomite, refractory clay, building stone and others.

On average, the manufacturing industry generates 17.5% of waste, over 69.2% of which come from the metallurgical industry (blast-furnace, steelmaking and ferroalloy slags and slurries, etc.).

The structure of metal-containing waste generated by the mining and metallurgical industries and accumulated at the managed dump-sites is shown in Fig. 5 and 6 [4, 5].

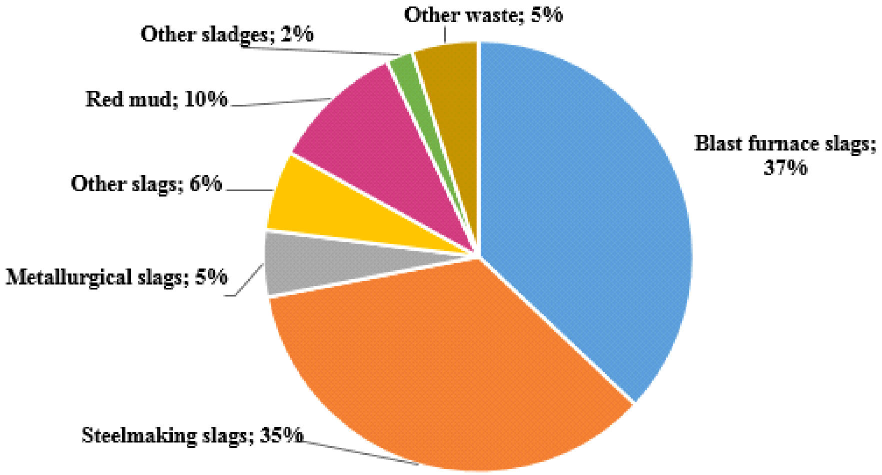

Fig. 5. Structure of waste generated from major metals production, %.

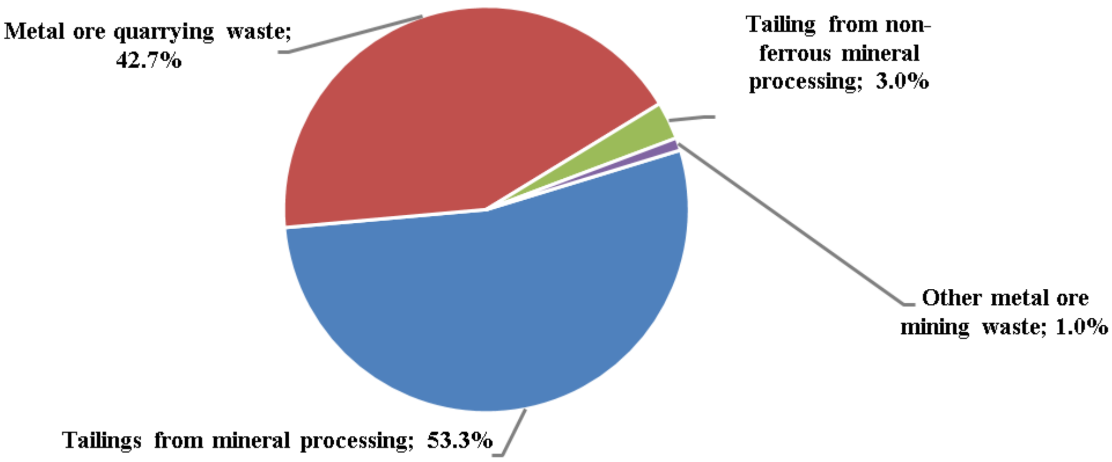

Fig. 6. Waste generated by metal ore quarrying and mining, %.

Fig. 7. Waste from iron ore quarrying.

https://doi.org/10.1051/e3sconf/202128009008

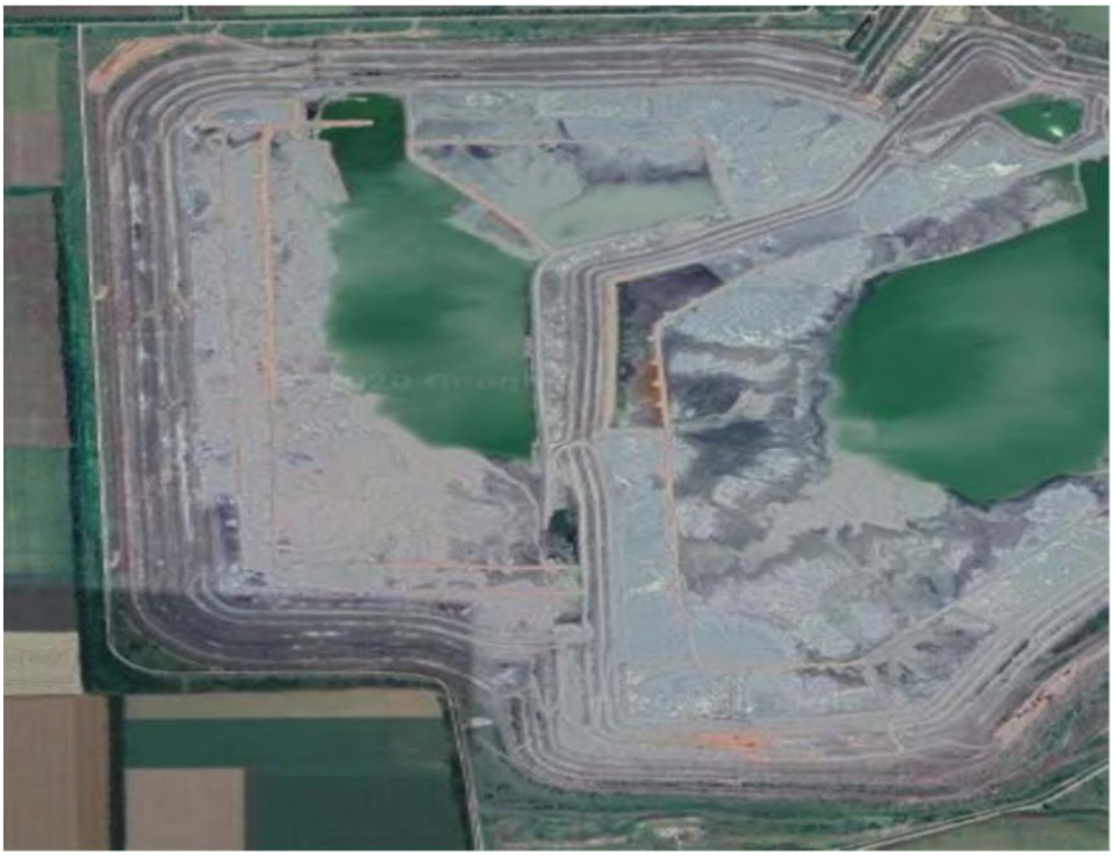

Fig. 8. Managed dump-sites with iron tailings.

Fig. 9. Waste from mineral processing of Irshansk Mining and Processing Plant.

The predominant part of the waste (78%) from major metals production is metallurgical and ferroalloy slags. Metallurgical sludge is the dust captured by air purifying equipment using liquid filters. It is stored in sludge collectors. After settling, the water is discharged into the surface water bodies, while the solids, if not reused, are accumulated at the managed dump-sites. Red mugs are generated at two enterprises – Mykolaiv alumina refinery and Zaporizhzhia alumina processing plants which produce alumina from bauxite. As can be seen from the chart (Fig. 6), the red mug makes 10% of the total waste from the major metal production.

One of the ways to reduce the amount of waste at the stage of extraction and processing of the metal ores in Ukraine is the integrated use of the mineral resources and the utilization of enrichment waste.

The chart shows that 96% of the waste generated by quarrying and mining is the metal ore waste and tailings from mineral processing (Fig. 7, 8).

The annual generation of iron tailings is over 130 mln. tons. Recycling of the tailings through ferrous concentrate and construction sand production will allow to decrease considerably the amount of the stored waste.

The problem of metal ore quarrying and mining in Ukraine is that host rock is not used. For example, in case of selective extraction and separate storage, talcum, garnet, muscovite and quartz concentrates can be produced from talc-, garnet- and muscovite-shales, respectively. Clays can be used for production of expanded clay and ceramics. The host rock can also be used for production of building sand and natural pigments (ferrous oxide, ocher, seladonite etc.). Mineralogy and chemical composition of some host rocks have been studied and described in detail in [7-12, 14, 15].

Clay, sands and limestone-shells from the overburden can be attributed to the resource potential of the manganese ore production waste in Ukraine, which can be selectively extracted and subsequently used in the national economy. In addition, more than 400 million tons of manganese-containing sludge have been accumulated in sludge storage facilities, with a mass fraction of Mn 10.5 - 17.5%. By sludge processing applying different schemes, it is possible to obtain manganese concentrate with a mass fraction of Mn from 35-41% (high-gradient magnetic separation with flotation) to 50% (magnetic-chemical technology) with an extraction of Mn 65-68% and 64%, respectively.

The enrichment waste prevails in the total amount of wastes from extraction and enrichment of heavy mineral titanium-zirconium sands. The overburden from the development of titanium-zirconium placer deposits in Ukraine (clay, loam, sand) is acceptable to be used for reclamation works.

Ore minerals in the technogenic sands of the Malyshevskyi deposit (the Volnogorsk MMC) are represented by zircon, rutile, leucoxen and ilmenite. Mostly they are concentrated in the fraction – 0.16 + 0.06 mm. Disten, sillimanite, staurolite and tourmaline have relatively significant contents.

Studies of the material composition of the waste from the Irshansk group of deposits have revealed that 60 wt.% of sands are represented by 0.5-0.125 mm grains; 5-15 wt.% is the metallic fraction, 85-95 wt.% – the non-metallic one. The ore minerals are mainly ilmenite, rutile, ilmenorutil and zircon. The presence of zircon as the main mineral carrier of zirconium is confirmed by the mass fraction of the latter in the waste (0.05 - 0.5 wt.%). We consider that these technogenic sands can be used to produce titanium and zirconium as well as quartz sand (Fig. 9).

Eurostat and the State Statistics Committee of Ukraine keep records of waste generation by material as well. Subdivision of wastes by material based on EU and Ukrainian data (2016) is presented in Table 3 [2, 3].

Table 3. Waste generation by waste category in Ukraine and EU countries.

As indicated in table 3, over 2 billion tons of waste is generated annually in EU countries. The total volume of waste generated in all 28 EU countries in 2018 was 2.6 billion tons. Mineral and solid waste constitutes the largest part of the total waste generated in all countries – from 39.9% in Italy to 80.9% in France. In Ukraine, they constitute 76.4% of the total waste generated.

In the EU countries, various amounts of waste are generated from waste recycling – from 6% in Netherlands to 16% in the United Kingdom. In Ukraine, the amount of waste from waste recycling is only 0.07%.

Fig. 10 shows waste accumulation at managed dump-sites in different regions in Ukraine [3].

The chart shows the amount of waste accumulated at managed dump-sites in different regions in Ukraine. Based on this amount the regions were divided into 3 groups. The first includes areas accommodating hundreds of millions of tons of waste. The second – tens of millions of tons. The third – less than 10 million tons.

Having the well-developed industry Dnipropetrovsk region accommodates the largest volumes of waste. The plants extract and enrich iron, manganese, titanium-zirconium ores and coal. There are also metallurgical and ferroalloy plants.

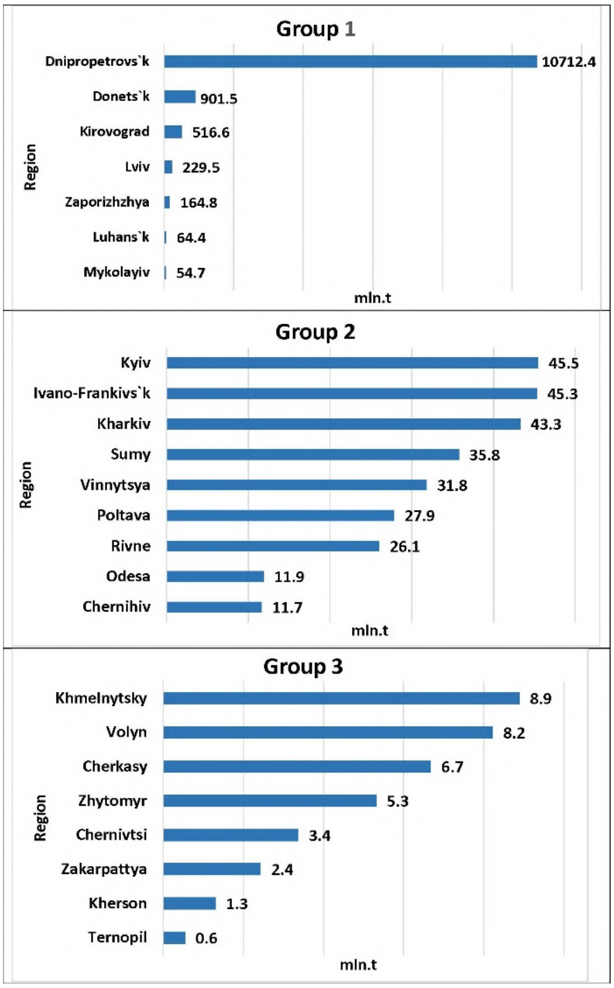

Fig. 10. Waste accumulation in different regions in Ukraine.

As can be seen from the chart, Dnipropetrovsk region accumulated 10 billion tons of waste at the disposal sites.

According to our estimates. More than 90% of it is waste from extraction and processing of iron and manganese ores (Kryvbas mining and processing integrated plant. Nikopol manganese ore field and metallurgical plants).

In Donetsk region, at the territory controlled by the Ukraine authorities most of the waste is accumulated at the coal mining and enrichment plants, coke plants and metallurgical plants. Dokuchaiv flux-dolomite plant which accumulated huge amounts of waste by 2013 is located at the temporarily occupied territories and the data are not available.

In Kirovohrad region, 99.9% of waste is accumulated at three enterprises: Petrivskyi quarry of the Central mining and processing complex, gulch “Shcherbakivska” and mine “Inhulska” of the Eastern mining and processing plant. Petrivskyi quarry’s disposal sites accommodate almost 80% of the waste accumulated in Kirovohrad region.

In Lviv region over 96% of waste is accumulated at four enterprises: JSC “Lviv Coal Company”. 6 mines of SE “Lvivvuhillia”. Novoiavorivske SE “Ekotransenergo” and Dobrotvirska TPP.

In Zaporizhzhia region almost 90% of waste was accumulated at 5 enterprises. i.e. JSC “Zaporizhstal” (metallurgical (iron) slag and sludge). Zaporizhzhia TPP (coal ash). LLC “Remondis Zaporizhzhia” (household waste). JSC “Zaporizhzhia Ferroalloy Plant” (ferroalloy slag and dust from gas purification plants) and JSC “Zaporizhzhia Aluminum Production Plant” (over 10 million tons of red sludge).

In Luhansk region, at the territory controlled by the Ukrainian authorities there are coal enterprises which generate coal mining and enrichment waste.

The second group comprises the Ukrainian regions which accommodate the most powerful TPPs (Trypilska, Zmiivska, Ladyzhynska and Burshtynska). These TPPs produce 60-70% of the total waste generated in a region.

The third group includes regions in which 70-99% of the total waste is municipal waste.

It should be noted that the volume of accumulated waste in Ukraine is much higher than the mentioned above. This is because the State Statistics Service receives information only from operating enterprises. Large volumes of waste are stored at enterprises abandoned after disintegration of the Soviet Union.

According to the Ministry of Energy and Environmental Protection data, 35 billion tons of waste have been accumulated in the country. 14 of the largest waste generators are located in Dnipropetrivsk region, 9 - in Donetsk, 3 - in Poltava, 2 in Kirovohrad and Zaporizhzhia and 1 in Ivano-Frankivsk, Mykolaiv, Ternopil and Lviv regions.

6 out of 35 largest waste generators are Kryvbas mining and processing enterprises which exploit iron ore deposits (Table 4) [6].

Table 4. Largest waste generators and polluters of the environment in Ukraine.

№	Company name	Generated waste. mln. tons
1.	Northern Mining and Processing Plant	81.34
2.	Inhulets Mining and Processing Plant	63.48
3.	Central Mining and Processing Plant	61.56
4.	ArcelorMittal Kryvyi Rih	27.65
5.	Southern Mining and Processing Plant	26.92
6.	Yerystivskyi Mining and Processing Plant	14.95
7.	Novotroitske Ore Mining Company	6.74
8.	Ilyich Iron and Steel Works	6.23
9.	“Ukrmechanobr” Ore Mining and Processing Integrated Plant	3.86
10.	Pokrovskyi Mining and Processing Plant	3.26
11.	Total	**295.99**

The enterprises listed in the table except for PJSC “Ilyich Iron and Steel Works” are the mining and processing plants that predominantly accumulate overburden iron and manganese ore enrichment waste.

In Ukraine, 14 mln. tons of iron ore waste from mining and processing plants are dumped on over 7 thousand hectares. The article [13] presents a list of alternative minerals which can be extracted from Kryvbas iron ore deposits. Technologic solutions for waste management and mineral extraction from tailings and host rock are described in the papers [16-18]. Enrichment technologies have been developed under laboratory conditions.

The problem of complex use of the deposits in order to reduce technogenic impact is predominantly the economic and political one. Extraction of iron ore concentrate from the enrichment waste at the Central mining and processing complex (Kryvyi Rih) has shown that its cost is 40% lower than the concentrate extracted from the quarried ore; its quality is only slightly lower.

We believe that it is possible to reduce the technogenic impact on the environment by recycling of tailings and more comprehensive and effective use of mineral deposits.

3 Conclusions

Analysis of industrial waste showed that the amount of its generation in Ukraine correspond to that in France. Poland and Romania (300-400 million tons per year). In Ukraine the largest amounts of waste are generated from the quarrying and mining (74.3%). and manufacturing (13.2%) industries. In Germany and France, for example, the largest amount of waste is generated from construction (55.6% and 70.2%. respectively), manufacturing (13.9% and 6.6%. respectively) and waste/water (11.9% and 6.8%. respectively).

The impact of industrial waste from mining and mineral processing on the environment can be reduced by application of innovative technologies in ore extraction and enrichment and in metallurgical industry. It will increase the degree of extraction of useful components from the mineral resources and improve the monitoring of waste disposal sites. Solution of the above problems depends on the legislation and the willingness of business to invest in diversification of production.

Abstract. The analysis of the impact on the ecology of the state of cybersecurity of critical infrastructure objects and the factors influencing the state of cybersecurity of the information system of the critical infrastructure object is performed. An explanation is given of why cybersecurity violations in automated process control systems can lead to consequences in the industrial sector and environmental impact. The need to develop effective and adequate proposals and measures for cybersecurity of information systems of the critical infrastructure objects is shown. The classification of assets that are the objects of cyberattacks by attackers and the categories of impact on the critical infrastructure objects are given. Approaches to determining the cyber threat risk factor of the critical infrastructure object and the relevance of threats are presented. The method of assessing the degree of possible damage from the implementation of information security threats is considered. The results of this analysis can be used to develop proposals and measures to avoid the effects of cyberattacks on the critical infrastructure objects. The prospect of further research is to develop a methodology for determining the relationship between specific cyberattacks and possible quantitative damage.

1 Introduction

The current stage of development of society is characterized by the introduction of new technologies, which is a sign of the level of economic development of the country. The growing role of the information sphere for the economy of the state is associated with its rapid entry into the communications, transport, energy, financial, defense and other spheres.

Strategically important for the functioning of the economy and security of the state, society and population are the critical infrastructure objects - enterprises and institutions (regardless of ownership) of industries such as energy, chemical industry, transport, information technology and telecommunications (electronic communications), food, health care, utilities. Therefore, given that in modern society cyberattacks are becoming more frequent and tend to have a significant and lasting impact through enterprises on the economy, it is undeniable that reliable protection against cyberattacks actively affects the state of economic, political, social, defense and other components, national security of the state [1].

It is obvious that the disruption of the critical infrastructure objects of the state can lead to emergencies related to deaths, environmental disasters, causing great material, financial, economic damage or large-scale disruptions of cities and towns, etc. In these circumstances, security, including cybersecurity of the critical infrastructure objects of the state, plays an extremely important role.

Unlike traditional IT systems, in Automated Process Control Systems, which operate on the critical infrastructure objects, there is a fairly close relationship between automated systems and physical processes and actuators [2]. Therefore, the violation of cybersecurity in the Automated Process Control Systems can lead to consequences in the industrial sector and environmental impact.

In view of the above, it is necessary to analyze the impact on the environment, and, as a consequence, to develop effective and adequate proposals and measures for cybersecurity of information systems (IS) of the critical infrastructure objects to prevent such impacts.

2 Analysis of previous publications

A significant part of publications, in particular [3-8], is devoted to the study of problems related to the environmental impact of the state of cybersecurity of IS of the critical infrastructure objects.

In [9-12] shows along with the benefits of accurate and economic control of these digital I&C systems comes the challenges of cybersecurity. Especially with the growth of industry-targeted cyber-attacks in both numbers and capabilities, an overall understanding of the current cybersecurity status is important for further cybersecurity research and deployment improvement. Cyber-attacks against critical energy infrastructure have gone from

* Corresponding author: sfgonchar@gmail.com

possible to eventual to actual. With electrical generation sources in the United States changing under a wide range of pressures, the current fleet of nuclear power plants in the United States provides a reliable and sustainable source of electrical generation capacity. However, in order to extend the lifetime of the fleet, modernization upgrades to digital instrumentation and control systems are required. While this produces many opportunities for increased efficiency, it introduces a new level of complexity for securing and reliably operating reactors in the presence cyber-threats. The United States Nuclear Regulatory Commission recently began urging stronger cybersecurity efforts at nuclear power plants. As upgrades at nuclear power plants begin, the implementation of digital instrumentation and control systems to monitor and run the power plant introduces new vulnerabilities that must be addressed. This necessitates a more modern discussion of risk.

However, today, for all its importance, the issue of the environmental impact of the state of cybersecurity of the critical infrastructure objects remains insufficiently studied and researched and is in urgent need of development.

3 The research results

Cyberattacks are aimed at damaging assets. An asset is an entity that is valuable to an individual, organization, or state. Therefore, security programs are aimed at protecting assets from damage.

Assets of the critical infrastructure objects can be classified by type as follows [13]: physical, logical, human.

Consider in more detail each of the types of assets.

Physical assets include any physical components or groups of components that belong to the organization. In the critical infrastructure objects, they include: control systems, physical components of the information transmission network or any other physical objects that are in some way involved in the management processes and analysis of production processes.

Logical assets may include intellectual property, algorithms, expertise, or other information elements that include the ability of an organization or innovation to function. In addition, these types of assets may contain a public reputation, customer confidence, or other measures that, if damaged, directly affect the production process. Logical assets may be presented in the form of personal memory, documents, information contained on physical or electronic media and include test results, regulatory data, or any other information that is treated as confidential or private. Loss of logical assets often causes significant damage to the organization for a long time.

IS of the critical infrastructure objects assets are a special form of logical assets. They contain the logic of automation, which is involved in the implementation of production processes. These processes are highly dependent on the repetition or continuous execution of well-defined events. Therefore, damage to these assets, such as removal or unauthorized modification, may result in loss of integrity or availability directly to the process itself.

Human contain people, knowledge, as well as theoretical and practical skills that they possess and that are related to their production activities. These may include the necessary certificates or important skills needed to act in an emergency.

Assessment of asset losses can be expressed either quantitatively or qualitatively [13].

A quantitative assessment of an asset provides an accurate answer about the financial costs associated with that asset. This may be the replacement cost, the value of the lost sale or other monetary policy measures.

Qualitative valuation of assets is usually expressed more at the abstract level, such as percentages or relative values. Many assets can only be analyzed in terms of qualitative losses.

Losses in IS of the critical infrastructure objects can be classified as direct and indirect.

Direct losses are costs that are associated with the replacement of assets. Damage may occur due to physical damage to the asset, as a result of loss of integrity or availability, interruption of the exact sequence or change in the nature of the process. Logical assets have relatively low direct losses in relation to their usefulness, because the media used to store the asset, as a rule, has a low cost. Minor damage to human assets with a short recovery time can have low direct damage to the organization, even in the case of long-term consequences for the injured person.

Indirect losses are losses caused by loss of assets. These may include losses associated with downtime, recycling or other production costs due to loss of assets.

For physical assets, indirect losses typically include the consequences that arise from the loss of components. Indirect damage from equipment damage may result in repairs, reengineering, or other efforts to regain control of the industrial process. For logical assets, indirect losses are often very large. These include loss of public confidence, loss of business license, loss of competitive advantage from the issuance of intellectual property, such as confidential process, new technologies and so on.

You can correlate the types of losses for each type of assets by sorting the above data by type of assets and the way of expressing their valuation.

The danger of cyber threat in the critical infrastructure objects automated systems from many threats will be determined by assessing the possible consequences of its implementation from the standpoint of impact on the operation of the critical infrastructure objects automated systems, and the severity of such consequences - the risk factor of this threat [14].

Each threat to the cybersecurity of information system circulating in the information system of the critical infrastructure object can be described as follows:

$$n = f\{Z_n, U_n, K_n, H_n, C) \quad (1)$$

where Z_n is the source of the nth threat to cybersecurity of the information system;

U_n - vulnerabilities due to which it is possible to implement the nth threat to cybersecurity of the information system;

K_n - favorable conditions for the implementation of the *n*th threat to cybersecurity of the information system of the critical infrastructure object of the energy sector;

H_n - consequences of the implementation of the *n*th threat to cybersecurity of the information system of the critical infrastructure object;

C - assets of the critical infrastructure object, which may be damaged in the event of the *n*th threat to cybersecurity of the information system.

The threat to the security of information circulating on the critical infrastructure object will be considered relevant if for the specified object of critical infrastructure with the set structural and functional characteristics and features of functioning there is a probability of realization of the considered threat by the intruder with the appropriate potential and its realization will lead to unacceptable losses from violation of confidentiality, integrity or availability of information.

This is due to the fact that in automated systems of the critical infrastructure object there is a very close relationship between automated systems and physical processes and actuators [14]. Therefore, information security breaches in these systems can have consequences in the industrial sector.

Given the above, the risk of threat in automated systems of the critical infrastructure object from many threats will be determined by assessing the possible consequences of its implementation from the standpoint of impact on the operation of automated systems of the critical infrastructure object, and the severity of such consequences - the risk factor of this threat [14].

The relevance of the *n*th threat to cybersecurity of the information system in general can be described as follows:

$$A_n = f\{P(H_{nu}|K_n); H_n\} \tag{2}$$

where $P(H_{nu}|K_n)$ is the probability of realization of the *n*th threat using the *u*th vulnerability, provided there are favorable conditions for this K_n; H_n - the consequences of the implementation of the *n*th threat to cybersecurity of the information system of the critical infrastructure objects.

The probability of a threat can be determined based on the analysis of statistical data on the frequency of information security threats (occurrence of security incidents) in automated systems of the critical infrastructure objects and / or similar systems.

In the absence of such statistics, the relevance of the threat is determined by assessing the feasibility of the information security threat, which in turn is determined by assessing the level of security of automated system of the critical infrastructure objects and the potential of the intruder required to implement the threat.

The hazard ratio can be determined by assessing the extent of the consequences of the breach of confidentiality, integrity or availability of information in automated systems of the critical infrastructure objects.

The relevance of information security threats is determined in relation to the threats for which the following is determined by the expert method:

- opportunities (potential) of the intruder are sufficient to realize the threat to information security;

- in the automated system of the critical infrastructure objects there are potential vulnerabilities that can be used in the implementation of a certain threat to information security;

- structural and functional characteristics and features of the functioning of the automated system of the critical infrastructure objects do not exclude the possibility of using the methods necessary to implement a particular threat, i.e. there is a scenario of threat realization;

- the implementation of the threat to information security will lead to a violation of confidentiality, integrity or availability of information, which may result in unacceptable negative consequences, causing significant harm.

Sources of information on the initial data on information security threats and their characteristics can be basic and standard models of information security threats, defined by regulations for different classes and types of automated systems.

Let's estimate the probability of realization of the threat to information security. The probability of information security threat will be understood as an indicator determined by an expert, which characterizes the value of the probability of realization of a certain (*n*th) information security threat in the automated system of the critical infrastructure object with specified structural and functional characteristics and features. For this purpose it is necessary to enter gradations of this indicator concerning the nth threat which can be described as follows:

$$P(R_n) = f(K_n; S_n; q_n; \omega_n) \tag{3}$$

where K_n - the presence or absence of favorable conditions for the implementation of the *n*th threat;

S_n - the presence or absence of the necessary statistics on the facts of the *n*th threat (the occurrence of incidents of cybersecurity violation of the information system);

q_n - the presence or absence of potential intruders of motivation to implement the *n*th threat, internal and / or external destabilizing factors, i.e. the model of the intruder and the threat model of the information system of the critical infrastructure object of the energy sector;

ω_n - the possible frequency of the *n*th threat.

In the absence of the necessary data to assess the probability of implementation of information security threats or doubts about the objectivity of expert assessments in determining the gradations of the probability of information security threats, the relevance of the *n*th information security threat is determined by assessing its feasibility.

The possibility of implementing the *n*th threat to information security can be assessed based on the level of security of the automated system and the potential of the intruder required to implement this threat to information security in the automated system of the critical infrastructure object with specified structural and functional characteristics and features. Therefore, the possibility of realizing the *n*th threat can be described as follows:

$$W(H_n) = f(X_n; Y_n) \qquad (4)$$

where X_n - the level of protection of the automated system of the critical infrastructure object for the implementation of the *n*th threat; Y_n - the potential of the intruder required to implement the *n*th threat, i.e. the threat model.

It is obvious that when putting an automated system of the critical infrastructure object into operation, a high level of protection from the intruder with a given potential must be provided.

However, in the course of operation of automated systems of the critical infrastructure objects new vulnerabilities of systems, increase of potential of the intruder, change of structural and functional characteristics, importance of the processed information, features of functioning of the specified systems and other conditions leading to emergence of new threats to information security can significantly reduce the level of design security of these systems. In this case, in order to maintain the level of protection of automated systems of the critical infrastructure objects during operation, a regular analysis of changes in information security threats should be conducted, and current information security threats should be periodically re-evaluated.

Thus, the level of security of the automated system of the critical infrastructure objects can be determined based on the analysis of the following information:

- whether there are additional threats to information security during operation;
- whether information protection measures can be taken against additional information security threats that have arisen during operation;
- how quickly you can neutralize additional threats to information security that have arisen during operation.

The potential of the intruder to implement a particular threat to information security can be determined on the basis of data provided in the basic and standard models of information security threats, which are determined by regulations for IS of different classes and types.

To assess the degree of possible damage from the implementation of information security threats, the possible outcome of the information security threat in the automated system of the critical infrastructure objects, the type of damage that can lead to the implementation of information security threats, the degree of consequences of the implementation of information security threats for each type of damage.

As a result of the threat to information security, direct or indirect effects on the confidentiality, integrity, availability of information circulating in the automated control system of the critical infrastructure objects are possible [14].

Direct impact on the confidentiality, integrity, availability of information is possible as a result of the implementation of a direct threat to information security. In this case, the objects of the threat are directly information and / or other objects of protection that ensure the receipt, processing, storage, transmission, destruction of information in automated systems of the critical infrastructure objects, as a result of access to which or impact on which the impact on privacy, integrity or availability of information is possible.

Indirect impact on the confidentiality, integrity, availability of information is considered as a result of the implementation of indirect threats to information security. The implementation of indirect threats to information security does not directly affect the confidentiality, integrity, availability of information, but creates the conditions for the implementation of one or more direct threats to information security, which allow to implement such an impact. In this case, as a result of the implementation of an indirect threat, it is necessary to consider the results of the implementation of all direct threats to information security, which can be implemented in the case of the implementation of this indirect threat.

In determining the degree of possible damage, it is necessary to assume that depending on the goals and objectives of the automated system of the critical infrastructure objects, types of information processed, the impact on confidentiality, integrity or availability of each type of information contained in the system may lead to different types of damage. In this case, different owners of information will be characterized by different types of damage.

As noted in [13], the main categories of influence in automated control systems of the critical infrastructure objects are:

- physical impact - includes many direct consequences of accidents of the Automated Process Control Systems. The most important potential consequences are those that can lead to injury and death. Other consequences include loss of property (including data) and potential damage to the environment;
- economic impacts - the consequences of the second order from the physical impacts that are derived from accidents of the Automated Process Control Systems. Physical impact can have consequences for the system, which in turn can cause greater economic damage to the enterprise or organization. On a large scale, these effects can negatively affect the local, regional, national levels, and possibly the global economy;
- social influences - the consequences of the second order, which are derived from the loss of state or public confidence in the organization.

Given the above categories of impacts in automated control systems of the critical infrastructure objects, it is possible to list the consequences of these impacts [13]:

- violation of national security;
- facilitating the commission of an act of terrorism;
- loss or reduction of production;
- injuries or deaths;
- damage to equipment;
- emission (leakage, evaporation) or theft of hazardous materials;
- environmental damage;
- criminal or civil obligations;
- loss of private or confidential information;
- loss of brand image or customer trust.

These consequences may be supplemented by other types depending on the goals and objectives solved by the automated system of the critical infrastructure objects, as well as the type of information that is processed in it.

The degree of possible consequences of the implementation of information security threats is determined by the degree of negative consequences of the violation of confidentiality, integrity or availability of each type of information circulating in the automated system of the critical infrastructure objects.

Thus, the degree of negative consequences of breaches of confidentiality, integrity or availability of information is determined for each type of damage, depends on the goals and objectives performed by the automated system of the critical infrastructure objects, and may have different meanings for different information owners and operators, and is determined by experts.

If two or more types of information are processed in an automated system of the critical infrastructure objects, the degree of possible damage must be determined separately for each type of information circulating in the system. The final degree of possible damage will be determined by the highest value of the degree of possible damage, determined for the confidentiality, integrity, availability of each type of information.

Every cyber threat, if implemented, leads to destructive ones. The relationship between threats and destructive actions that arise as a result of the implementation of these threats can be represented as a matrix:

$$G = [g_{dn}] \tag{5}$$

where d varies from 1 to D; D - the number of possible destructive actions; n varies from 1 to N; N - the number of cyber threats.

The elements of the matrix (5) become 1 if the nth cyber threat leads to the implementation of the dth destructive action, and become 0 - otherwise.

Let B_d be the coefficient of danger of performing the dth destructive action, where d varies from 1 to D; D - the number of possible destructive actions.

Then, given that in the case of the implementation of the nth cyber threat may be several destructive actions, the risk factor of the nth cyber threat will be determined as follows:

$$B_n = \Sigma B_d g_{dn} \tag{6}$$

where B_d – the coefficient of risk of execution of the dth destructive action, determined by the severity of the consequences of this execution, as an indicator of the criticality of the energy sector; g_{dn} – a coefficient that is defined as an element of the matrix (5).

The analysis of existing information security systems allows to determine the main components of the cyber security system of information systems of the critical infrastructure objects:

- normative-legal;
- organizational;
- technical;
- training, retraining and advanced training of relevant specialists.

Each of the above components, in one way or another, affects the state of cybersecurity of IS of the critical infrastructure objects.

Thus, one of the topical issues is the availability of regulatory framework for cybersecurity of IS of the critical infrastructure objects, bringing the national regulatory framework for cybersecurity of the critical infrastructure objects in line with international regulations; fulfillment of the coherence of the conceptual apparatus used in the existing national legislative and regulatory documents; finalization (if necessary - development) of regulatory documents, requirements, methodologies for threat assessment of facilities that are critical to the life of the state, the general methodology for risk assessment for critical facilities and critical infrastructure in general.

In addition, it should be noted that managers and / or owners of the critical infrastructure objects should be aware of the possibility and likelihood of cyberattacks and the consequences, if any. The implementation of cybersecurity measures requires additional resources, to which the managers of these objects do not always agree, and there is no mechanism that would require these managers to implement the necessary measures. Therefore, without the introduction of this mechanism, all standards, instructions, etc. on cybersecurity of IS of the critical infrastructure objects will be of a recommendatory nature, because the information circulating, for example, in Automated Process Control Systems, does not belong to any type of information subject to protection in accordance with applicable law.

Cyberattacks of an external intruder are opposed by the information protection system of the information system of the critical infrastructure objects, the functions of which must include:

- protection of the network perimeter;
- ensuring the security of interconnections;
- security monitoring and audit;
- detection and prevention of attacks;
- data backup and recovery;
- security analysis and security policy management;
- data integrity control;
- protection against malicious software;
- content filtering and prevention of leakage of confidential information;
- installation of software updates;
- security administration.

According to the results of the analysis of threats and vulnerabilities [13], it can be noted that the protection of such systems should be considered in the following areas:

- protection of information and physical components of IS of the critical infrastructure objects;
- technical information protection of IS of the critical infrastructure objects;
- protection of processes, procedures and programs of information processing of IS of the critical infrastructure objects;
- protection of communication channels of IS of the critical infrastructure objects;
- suppression of spurious electromagnetic radiation;
- management and control of the protection system.

Thus, taking into account the above, it can be noted that the state of cybersecurity of IS of the critical infrastructure objects is influenced by the following factors:

- availability of the necessary and sufficient regulatory framework for cybersecurity of IS of the critical infrastructure objects;
- the presence of sources of cyber threats, their capabilities, type, purpose, motives, interest in cyberattacks;
- the presence of vulnerabilities in cyber defense systems that can be used in cyberattacks;
- the presence or absence of favorable conditions for the implementation of cyber threats;
- the attractiveness of the assets to which cyberattacks are actually directed;
- consequences of the possible implementation of cyber threats;
- the level of professional training of employees responsible for cybersecurity at all levels: organization, enterprise, industry, department, etc.

4 Conclusions

The analysis of the ecological impact of the state of cybersecurity of the critical infrastructure objects and the factors influencing the state of cybersecurity of the information system of the critical infrastructure object is performed. The method of assessing the degree of possible damage from the implementation of information security threats is considered.

The results of the analysis can be used to develop proposals and measures to avoid the effects of cyberattacks on the critical infrastructure objects.

The prospect of further research is to develop a methodology for determining the relationship between specific cyberattacks and possible quantitative damage.

Abstract. Based on the results of actual multi-year measurements of wind speeds, numerical calculations have been made of the forecast energy productions of 43 megawatt-high power stations of the leading world producers in the wind conditions of the North Black Sea region of Ukraine. The established correlation between the annual energy production of wind power station (WPS) and its basic parameters (nameplate capacity, diameter of the rotor and hub height) allowed to develop a mathematical model of the forecast annual energy production of WPS. The calculations for the mathematical model are well in line with the operational parameters of the generation. The mathematical model makes it possible to quickly and reliably select (or design) the optimal wind turbine for industrial wind power in the North Black Sea, thus taking a significant step in reducing the energy dependency, environmental protection and the transition to energy-efficient and environmentally friendly technologies enabling Ukraine to reach the level of advanced states in the development of wind energy.

1 Introduction

1.1 Problem statement

Wind energy (WE) is considered to be one of the promising sources of renewable energy at the present stage of energy development in economically developed countries. This fact guarantees the harmonious development of the planet. The Paris Agreements (Paris, December 2015) have identified renewable energy as the leading instrument in the fight against climate change on the planet. This is becoming one of the main areas of technology development in the world. Along with information and nanotechnology, renewable energy is becoming an important component of the new post-industrial technological structure. Ukraine urgently needs to switch to energy-efficient and environmentally friendly technologies, including WE.

Ukraine is a country with a long tradition of using wind. In the first two stages of the global development of renewable energy, it was a significant success. In the third stage, which began in the early 80s of the last century, Ukraine, which has a high wind potential, began the industrial use of wind with almost 40 years behind world leaders [1].

The wide-scale building of wind power stations (WPS) in Ukraine will make it possible to take a significant step in reducing energy dependence, protecting the environment and creating conditions for the country to join the European community.

By building efficient industrial WPS, the WE of Ukraine can and should be brought to the level of the advanced countries of the world with generation of 25–35% of the total energy consumption, which is of great social and economic importance. Some countries have already done so. Their share of electricity generated by WPS has reached: in Denmark – about 50 %, in Uruguay and in Ireland – more than 25 %, in Portugal – 23 %, in Germany – 20 %, in Spain – 18 % [2]. In the European Union WE since 2016 became the second (after natural gas) source in electricity generation [3]. However, this can be done only after solving the most important scientific and applied problem of the rational choice of multi-megawatt-class wind turbines (WT) for the wind conditions of Ukrainian wind parks.

1.2 The relevance and purpose of the work

Problematic issues of mathematical and computer modeling the parameters of large WT are far from being resolved. The choice of effective WT in Ukrainian wind conditions, which should generate as much commercial energy as possible and satisfy the price/quality ratio, remains open. This significantly limits the reliable selection of WT for a specific construction site of industrial WPS and does not contribute to closing Ukraine's lag behind world leaders. Therefore, the development and implementation of industrial wind energy in the strategic plan for the modernization of the electric power industry is super relevant, the most promising and priority.

* Corresponding author: vl.terekhov86@gmail.com

The purpose of the work is the development of methods and computer tools for optimizing the operational parameters of industrial WT in the wind conditions of Ukraine.

2 Materials and methods

2.1 The analysis of factors affecting the performance of WT

An analysis of literature on systematic studies of wind use with the main task to identifying factors that influence the efficiency of WT and the current state of research on the scientific and applied problems of mathematical and computer modeling of large WT has been carried out.

In the works of P.F. Vas'ko et al. [4–6 et al.] proposed a method for determining the performance indexes of WT in relation to the wind conditions of Ukraine. The method is based on the approximation of the empirical dependences of the wind speed repeatability using the three-parameter Weibull-Gnedenko distribution (WGD).

The most important influence factor in this method is the repeatability of wind speeds at the WT installation areas, which is one of the main components of the wind energy cadastre. It shows how much of the time during the working year winds at a certain speed are observed. It is the repeatability of wind speeds that largely determines WT performance.

Offered in the works of P.F. Vas'ko recommending for determination the repeatability by either conducting wind measurements followed by correlation according to the nearest weather stations (WS) over the past 12 to 15 years, or their approximate receipt by extrapolating data from the nearest WS, it is absolutely unacceptable for large WT. Indeed, these WS's data characterize the wind potential very approximately and cannot be used in assessing the performance of WT (WPS). The author himself agrees that the direct use of the WS's initial data causes significant errors in determining the annual generation of electricity. And confirms this with examples: for the Ochakov WS's data the results are reduced by 36 %, and for the Odessa WS – by 180 % in comparison with the open area [5].

The problem of finding the repeatability of wind speeds in the world is solved in different ways. In Japan, for example, this problem first solved it in two stages: at the first stage, the wind speed and direction were recorded for several years; on the second, a landscape model in an aerodynamic tube was purged. Based on the data obtained, the wind energy cadastre was determined for any point of the simulated landscape [7].

Much later, evaluating the sea prospect of wind around Japan for offshore WPS, measurements were organized in two places: offshore - on a platform for natural gas extraction in the Pacific Ocean at the height of 94 m, in 37 km from the coast and directly on the coast. Average annual and monthly wind speeds were calibrated for a height of 80 m above sea level to provide a comparison between offshore and land measurements. Simultaneous three-year measurements showed that the average annual sea wind speed is 70% higher than on land [8].

The atlas of winds has been developed in Denmark, in which this task is solved on the basis of models that take into account various factors of the orography of the area and data of the WS [9].

The creation of such an atlas for the wind conditions of Ukraine, as well as the use of Japanese experience, are associated with high material costs and unacceptable for Ukrainian conditions.

The problem of finding promising areas for WT installation has not yet been completely solved and remains relevant for many regions [10-12]. It requires a directed study of the wind regime of territories not only near the earth's surface, but also at different heights of the atmospheric layers near the earth.

The disadvantage in the proposed by P.F. Vas'ko method is to use the coefficient $m = 1/7 = 0.143$, taking into account the change of wind speed with height in the surface layer of atmosphere. In modern large WT, the heights of the hub vary widely and the problem of restoring the wind regime at the same height where the hub located is extremely important. A number of works are devoted to its solution.

Hellmann [13] recommended up to a height of 16 m to take the value of this coefficient equal to $m = 1/4$, and for larger heights $m = 1/5$. In studies of 50-60 years of the last century, this coefficient was assumed to be constant and equal to 0.2 [14]. Researchers from the USA recommend values of the coefficient $m = 0.23 \pm 0.03$, and when averaging wind energy, they use $m = 1/7$. Recently, experts from the USA suggest using a logarithmic dependence, which, in contrast to the power law, gives almost average values between the extreme values of wind speed at low and large heights [15].

Actual values of the power index m for different regions vary significantly from 0.1 to 0.4 and even exceed the values of 0.6 and 0.7. Various engineering methods continue to be developed [16], but as a result, none of the m values gives a good approximation of the data for different WT locations, and therefore the problem of restoring the wind regime at a given height has not yet been solved.

It is not surprising that the recommendations of P.F. Vas'ko, repeatedly cited by various authors [17, 18 et al.], who proposed a scheme of zoning of the territory of Ukraine according to average annual wind speeds, which today has become the basis for the building of industrial WPS in Ukraine, cannot be fully used for WT of multi-megawatt power. After all, the work was carried out at the end of the 50s of the last century, more than 60 years ago, and was studied on WT of low and medium power using the database of the State Committee for Hydrometeorology, when there were not enough experimental and operational data, which inevitably led to significant errors. Therefore, the work contains dubious and erroneous conclusions and recommendations. For example: "An intensive change in the technically achievable wind potential is observed up to a height of 60 m, and then the intensity decreases significantly." Or: "To ensure the capacity factor of wind turbines in Crimea at the level of 0.3, the rational value of the diameter of the rotor and the rated power of the installation are 48 m and 600 kW, respectively" [19].

As follows from the publications (and it has already become a global tendency), the efficiency of WT increases due to the growth of their rated power. Our studies show that focusing only on the rated power parameter leads to significant losses in electricity production.

On the process of choosing a WT is influenced by many factors: rated power, diameter and height of the rotor axis, operating time in certain zones of the power characteristic, capacity factor (CF). Therefore, a necessary condition for competent synthesis is only a differential approach to assessing each of the influence factors.

2.2 Electricity production of large WT in wind conditions of the Northern Black Sea region

For predictive calculations of the volume of electricity generated by any WT, it is necessary to have data about the wind potential on the area where the WPS equipped with these WTs is located, and a characteristic of the WT itself, i.e., the dependence of the electric power of the WT on the wind speed at the hub height.

The building of an industrial WPS in the Northern Black Sea region is planned in areas adjacent to the Adzhigol pilot WPS (AWPS), for which the distribution of probabilities of wind speed gradations for a period of 18 years measurements at a representative military aerodrome's WS, as well as measurements of wind speed and direction at the AWPS area by a Logger # 9200 device for 26 months at heights of 27 and 31.5 m and simultaneous measurements at heights of 31.5 and 10 m has been done.

The average wind speed over many years' studies, received from measurements data of a representative WS, reduced to the measurement conditions at the AWPS area (the windvane height 31.5 m), is 6.0 m/s. This speed is assumed to be the smallest in the calculations by different methods, which provides the most reliable forecast for a long period of WPS operation [20, 21].

For carry out the calculations of the volumes of electricity production by various WTs, the gradations of wind speeds at the height of the windvane to the hub heights of the studied WTs has been recounted. For recalculations of wind speeds from one height to another, the Hellman's power law has been used [12, 13]:

$$V_H \ / \ V_V = (h_H \ / \ h_V)^m. \tag{1}$$

Were:

V_V – wind speed at the windvane height h_V = 31.5 m;

V_H – the desired wind speed at a hub height h_H of the studied WT;

m – the coefficient of the vertical profile of the wind speed. As special tests have shown, on average for wind in AWPS area m = 0.227.

Converting the expression (1) to

$$V_H = V_V\,(h_H \ / \ h_V)^m = V_V\,(h_H \ / \ 31.5)^{0.227}, \tag{2}$$

determine the wind speed on the hub height of the investigated WT.

So, for the hub height, for example, h_H = 65 m:

$$V_H = V_V\,(65 \ / \ 31.5)^{0.227} = V_V \cdot 2.06349^{0.227} = \\ = V_V \cdot 1.17873.$$

For WT with h_H = 100 m

$$V_H = V_V \cdot 3.1746^{0,227} = V_V \cdot 1.29982 \text{ etc.}$$

Using expression (2), it is possible to convert the data of the annual distribution of wind speeds in the region of the AWPS at a height of h_V = 31.5 m into the annual distribution of the recurrence of wind speeds at different hub heights of the studied WTs.

The calculation of the annual potential power generation has been carried out according to the formula:

$$Q_n = \sum P_i \cdot T_i. \tag{3}$$

where:

Q_n – annual electricity production (AEP), MW·h;

P_i – generated power in the i-th range of wind speed V_i on the hub height, kW (according to the characteristics of the WT power);

T_i – duration of the wind speed V_i of the i-th gradation.

The duration of the year in hours was 365 days·24 hours = 8760 hours.

As a result of numerical simulation, the following predicted values for generating electricity of 43 megawatt WTs of leading world companies Leitwind, Enercon, Mitsubishi, Vestas and Fuhrlander in wind conditions of the Northern Black Sea region of Ukraine has been obtained (table 1).

The most important distinguishing feature of the obtained parameters is the use of actual multi-year real measurements of wind speeds and the distribution of their probabilities by gradations at the AWPS area. This is precisely their main difference from those hypothetical meanings that various authors used earlier. Therefore, these quantitative parameters are the basis for further computer modeling.

By numerical simulations, a multifactor dependence of the expected calculated electricity generation of a specific WT has been established.

As a result of computer simulations in first time, it has been found that, for example, LTW77 and LTW80 wind turbines with a nameplate capacity of 1.5 MW produce more electric energy than turbine LTW70 with a nameplate capacity of 1.7 MW; turbine E82-2.0 more than turbine E70-2.3; turbines MWT92-2.4 and FL 2.5-100 is more than turbine V90-3.0; and turbine V90-1.8 is more than turbine V80-2.0 (table 1). It follows that when choosing an effective wind turbine, accounting only for the index of its nameplate capacity will lead to significant losses in electricity production.

2.3 Development of a mathematical model of annual electricity production

One of the main goals of the work is a statistical study of the influence of individual parameters (explanatory factors): rotor diameter, rotor axis height (hub height), nameplate capacity, etc. on the AEP of WT and on the development of a mathematical model (MM) for this dependence. The resulting MM will make it possible to purposefully select on the world market (or design) the most effective WTs for the wind conditions of a particular area during the building of an industrial WPS.

43	—‖—	3.2	121	120	12759	45.5

—‖— – the same; *P* – nameplate capacity; *D* – diameter of the rotor; *H* – hub height.

At first, a correlation analysis of the statistical influence of all parameters from table 1 on the AEP *Q*, and then their pairwise influence of one on the other has been carried out [22–25].

The AEP of the turbine *Q* (MW·h) was considered as an explained variable, and explanatory factors: *X1* – nameplate capacity (MW); *X2* – diameter of the rotor (m); *X3* – the hub height (m); *X4* – CF (%).

To identify the statistical relationship between all factors of the table 1, we calculated the correlation matrix [22, 23, 25] (for this, the tool “Correlation” from the MS Excel-17 has been used). As a result, the next correlation matrix (table 2) has been obtained:

Table 2. Correlation matrix.

	Q	***X1***	***X2***	***X3***	***X4***
Q	1				
X1	0.845	1			
X2	0.928	0.765	1		
X3	0.629	0.337	0.373	1	
X4	0.706	0.229	0.676	0.732	1

From this correlation matrix it can be seen that the determining factor in the AEP of a wind turbine *Q* is the diameter of the rotor *X2* (correlation coefficient 0.928 – very high correlation); the next effect has the nameplate capacity of the generator *X1* (correlation coefficient 0.845 – high correlation); then follows CF *X4* (0.706 – high correlation) and the hub height *X3* (0.629 – average correlation) [24]. The average and high values of the correlation coefficients between the explanatory factors *X1* and *X2*, *X2* and *X4*, *X3* and *X4* indicate the possible presence of partial multicollinearity between them [26]. This means that in the further construction of the simplest linear model of multiple regression for the dependence of *Q* from *X1*, *X2*, *X3* and *X4* of the form:

$$Q = Q_0 + a_1X1 + a_2X2 + a_3X3 + a_4X4\ , \qquad (4)$$

partial multicollinearity can lead to significant instability of estimates of the model parameters Q_0, a_1, a_2, a_3, and a_4. The instability can result in an increase in statistical uncertainty – the variance of the estimates of the model coefficients, i.e., specific values of the parameters estimates can vary greatly for different samples despite the fact that the samples are homogeneous.

Given the full multicollinearity for a strict linear functional relationship between *Q* and CF, we exclude *X4* from the model, which subsequently eliminated partial multicollinearity and ensured the significance of the model by Student. We have:

$$Q = Q_0 + a_1X1 + a_2X2 + a_3X3. \qquad (5)$$

As a result of the application of “Regression” tool from MS Excel, the following summary table 3 has been obtained.

The obtained model has a high coefficient of multiple correlation *R* of the explained variable *Q* with all the explanatory factors *X1*, *X2* and *X3* (0.9939); high coefficient of determination R^2, normalized to the number of model factors (0.9870); relatively small standard error (272.09 MW·h). The model is significant as a whole according by Fisher ($P_F < 2.04\cdot10^{-37}$). The level of significance of the coefficients for explanatory factors by Student is extremely small, that is, MM has no visible limitations.

The obtained MM has the next numerical form:

$$Q = -7126.25 + 1348.594\cdot X1 + 97.526\cdot X2 + 28.811\cdot X3. \qquad (6)$$

It has a simple meaning: an increase in WT nameplate capacity by 1 MW leads to an increase in AEP by 1348.594 MW·h; an increase in rotor diameter by 1 m leads to an increase in AEP by 97.526 MW·h; increasing the hub height by 1 m leads to an increase in AEP by 28.811 MW·h. Or equivalent to the output is that an increase in the rated power by 1 MW, that a 14-fold increase in the diameter of the rotor or a 47-fold increase in the hub height.

2.4 Conclusion. Comparison of model studies with results of operation

The reliability and admissibility of accepted idealizations in the development of any dynamic model of a real system can be verified and evaluated only by comparing the results of theoretical studies with experimental data. The industrial operation of the first WPS in the wind conditions of Ukraine provided rich experimental material. In a comparative study, we use the actual results of their operation to increase the degree of credibility and validity of the conclusions.

Using the first obtained MM (6), we will estimate the possible annual electricity generation by the Dmitrovka Wind Cluster (DWC) of the Ochakov Wind Park (WP), equipped with the 12 WTs FL 2.5–100 for a five-year period (table 4).

At the up part of the table (highlighted in bold), explanatory factors of influence are presented. *X1*, *X2* and *X3* for WT FL 2,5–100 and the explained variable is calculated: annual production Q_M = 8879 MW·h and CF = 40.5%.

In the down part of the table 5 shown the actual power production Q_O with the actual values of CF [27].

The annual values of Q_O are less than the values of Q_M (and this is quite natural, because downtime is inevitable for all kinds of reasons): a minimum of 11% and a maximum of 18% (an average of 14.4% over 5 years).

Given the real actual values of the availability factor (AF), these ratios decrease from a minimum of 3.4 to a maximum of 14.7 (an average of 8.4% over 5 years), which is a completely reliable result.

3 Results and discussion

Comparison of the results of theoretical research and industrial operation is a convincing and indisputable proof of the legality of the computer simulation of MM developed for the first time.

An invaluable practically important feature of the developed MM is the absence of additional direct measurements of various parameters when using it, in particular, it does not require processing of weather data from representative WS, which contributes to a significant reduction in errors. And this is due to the fact that its development is based on actual long-term measurements by the automated system Logger (USA) of wind speeds at the pilot AWPS and the actual power-law index for measuring wind speed by height, which significantly increased the reliability of the calculations.

4 Conclusions

Developed for the first time by the method of computer simulation MM allows:

- quickly and reliably determine the optimal WT in terms of the parameters that are offered on the world market for a specific industrial WPS in a certain area;

- to develop and manufacture the necessary wind turbine in the absence of a world wind turbine with the necessary technical characteristics.

Abstract. The authors propose an approach to assessing the possibility of stabilizing controlled impact on the ecological system, its climatic characteristics, within a limited space. Maintaining the necessary climatic parameters at an acceptable level ensures the stability of any ecosystem, the natural habitat of all living organisms, the preservation of biodiversity, including humans. The biggest potential threat is the rapid dynamics of global warming. Rising temperatures are the cause of extreme weather events, which directly affects environmental and food security. Given the urgency of the task, there is a need to study the controlled mechanism of influence on certain climatic factors in order to curb abnormal dynamics and bring the ecosystem into a state of stable equilibrium. The approach proposed by the authors is based on modeling the process of reducing the risk of crisis situations with abnormal fluctuations in ambient temperature. The mathematical model is represented by a system of ordinary differential equations, which is a consequence of the adaptation of Lagrange equations to oscillatory processes. The state of the studied climatic factor is matched by some random process, the amplitude of which depends on the values of the components of the control vectors and the function of external influence. The experimental parameter is ambient temperature. The problem was solved using statistical data for the Zhytomyr region (Ukraine). The main results of the simulation are to obtain a set of control vectors and functions of external influence, which will be taken into account in the information system for monitoring the environmental situation.

1 Introduction

The development of various spheres of human activity, especially technology, especially information, clearly contributes to the positive growth of the level of civilization in general, but at the same time carries a negative component, which at first seems invisible, and then often simply ignored. This component is the current environmental problems, the exacerbation of which is associated with the processes of negative anthropogenic impact. For example, the impact on natural processes of climate change in many regions of the globe, the trend of global warming, which, uncontrollably developing, lead to terrible catastrophic consequences.

This article is a continuation of previous research by the authors [1-4] and their colleagues [5-16] in the field of improving the efficiency of management decisions, environmental safety issues, development of appropriate software, etc.

The main purpose of previous author's study [2] is the presentation of the conceptual approach to the development of software tools for the analysis and synthesis of a geophysical monitoring systems model. To achieve this goal, two approaches are proposed to describe the interaction "humanity - the environment". The first approach is based on the use of "game principles". The "game principle" of humanity and the environment can be described using a system of ordinary differential equations, pre-determined with the phase coordinates and "controls" of the players, as "control" affects the phase coordinates. At the heart of the second approach, the environment is considered as a system characterized by fluctuations under the influence of anthropogenic load. Depending on the level of external influence, the system either returns to equilibrium or as a result of increasing the amplitude of oscillations is destroyed and not restored, which is equivalent to a catastrophic state. The paper [2] substantiates the model of the geophysical monitoring system based on the Lagrange equations for an oscillatory system with two or more degrees of freedom in the "factor space", and the model based on "game principles". Also shown the block diagram algorithm of the analysis and synthesis of geophysical monitoring systems models.

Some environmental, information, and other aspects of geophysical monitoring systems models are presented in papers [17-38].

For example, the author of [22] writes, that the

* Corresponding author: ak24avo@gmail.com

technosphere metabolizes not only energy and materials but information and knowledge as well. The article first examines the history of knowledge about large-scale, long-term, anthropogenic environmental change. Also, the author proposes that knowledge infrastructures for the Anthropocene might not only monitor and model the technosphere's metabolism of energy, materials, and information but also integrate those techniques with new accounting practices aimed at sustainability.

The paper [26] presents a variational approach to solving direct and inverse problems based on the joint use of mathematical models and data monitoring of processes of geophysical hydro-thermodynamics. This approach is used to solve problems related to environmental protection.

A good illustration of interconnected geophysical processes in the environment on the example of the Arctic region is shown in paper [30].

A lot of game models for particular issues of human-environment systems are shown in papers [31-38] and others. For example, authors [33] to illustrate the applicability of their results analyze stochastic models of evolutionary games, Lotka–Volterra dynamics, trait evolution, and spatially structured disease dynamics. Analysis of these models demonstrates environmental stochasticity facilitates the coexistence of strategies in the hawk–dove game, but inhibits coexistence in the rock–paper–scissors game and a Lotka–Volterra predator-prey model.

The extreme urgency of environmental (climatic) problems gives a significant impetus to the study of such processes in ecological systems. Therefore, in order to study the mechanism of climate control, there is an urgent need to develop mathematical and simulation models using information technology (including artificial intelligence systems) in the interests of the safe development of society. The complexity of creating a perfect information system for managing global climate parameters leads to a narrowing of the task to the local level of a particular region.

The aim of the article is to develop a conceptual approach to modeling natural processes in the problem of studying the mechanism of climate control.

2 Methods

To solve this problem, we present the environment in the form of a system, which is characterized by fluctuations under the influence of anthropogenic load. In this case, depending on the level of external influence, the system either returns to equilibrium or, as a result of increasing the amplitude of oscillations, is destroyed and not restored, which is equivalent to a catastrophic state [1]. Since the result of general warming is an increase in the average temperature of the planet's atmosphere, it is advisable to choose the climatic parameter is the temperature. Accordingly, the mathematical model should describe the process of temperature control within the specified limits for a certain time of year in the selected local space.

The construction of the mathematical model assumes the availability of the necessary information about the factors influencing the temperature of the atmosphere, as well as the nature of the seasonal temperature dynamics of the selected research region: Zhytomyr (Ukraine), winter, December 2019. It is taken into account that solar activity, in general, is a slowly changing function of time [17], as well as the temperature component due to the distribution of radioactive substances in the earth's crust, the cloud layer is generally stable over time, natural emissions (e.g. volcanic activity) of pollutants in the atmosphere is absent, the movement of air masses is moderate.

Analysis of statistical data allows us to outline the main assumptions of the model: 1) seasonal dynamics of the region's atmospheric temperature is fluctuating; 2) temperature oscillating process is random; 3) surface air temperature is a function of such factors as solar activity, distribution of radioactive substances in the earth's crust, air mass movement, the stability of the cloud layer, emissions of pollutants of natural and anthropogenic origin, etc.

In the first approximation, it is expedient to consider the surface temperature of the region as a function of the concentration of emissions of harmful substances of anthropogenic origin and time at fixed values of other parameters of influence and external function of the thermal influence of anthropogenic origin. Thus, the task is to study the dynamics of the component of the temperature regime of the surface layer of the atmosphere of the selected region, which is due to the level of emission concentrations of pollutants of anthropogenic origin (mobile and stationary emission sources) and their thermal effects.

3 Results and discussion

3.1 Formulation of the problem

Consider the temperature θ as a function of two parameters: $\theta(t, c_S)$, where c_S is the average monthly concentration (mg/m^3) of emissions of harmful substances into the atmosphere of anthropogenic origin, $t$is the time (from the first to the last day of the selected month). At a fixed value of c_S, we obtain the dependence of $\theta(t)$, Fig. 1.

Since the studied oscillatory process is random, it is expedient to describe it using a set of systems of second-order differential equations, which are a consequence of the adaptation of Lagrange equations to oscillatory systems [2]. In this case, one phase variable $c_S$is fixed, and the second phase variable $\theta(t)$ is controlled.

Then, within the framework of this goal, it is necessary to obtain a set of control vectors of the form $\vec{\varphi} = \begin{bmatrix} a_0 \\ a_1 \\ .. \\ a_n \end{bmatrix}$, as well as the function of the external thermal influence $W(t)$ for each implementation of the random process $\theta(t)$.

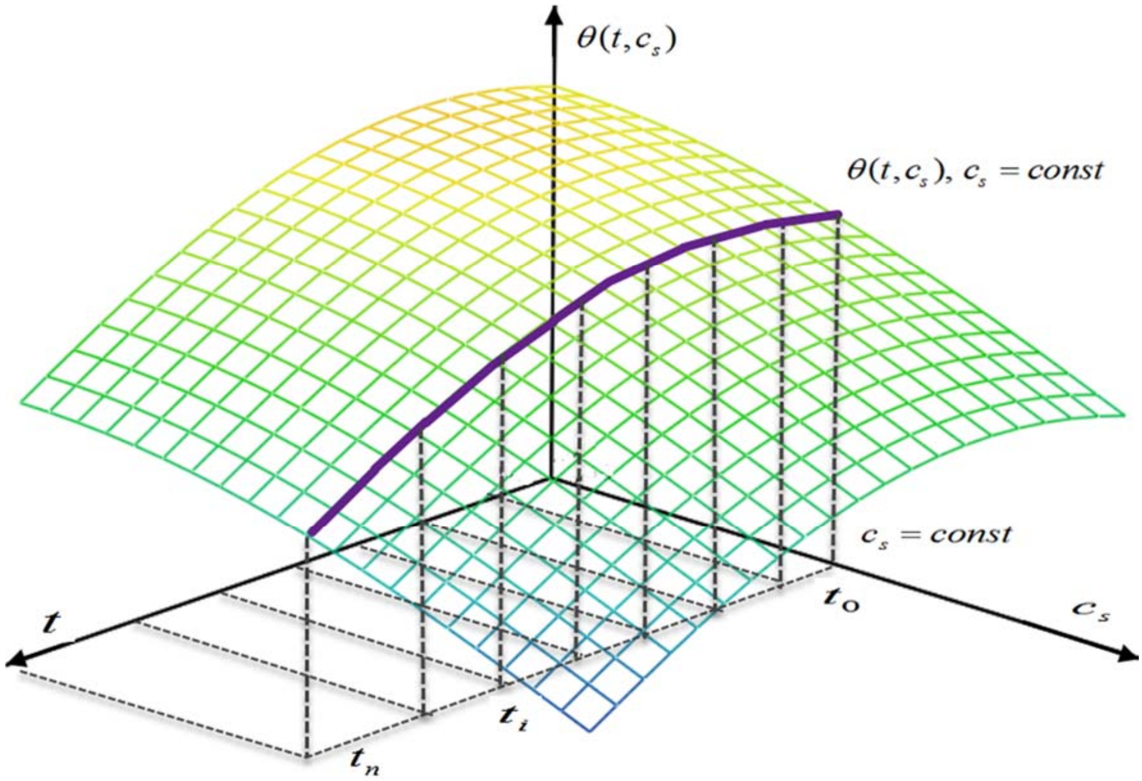

Fig. 1. Function $\boldsymbol{\theta(t, c_S)}$ at a fixed value of $\boldsymbol{c_S}$.

The values of the components of the set of control vectors $\vec{\varphi}$ must unambiguously ensure that the phase variable $\theta(t)$ is within certain limits, then the dynamics of the variable $\theta(t)$ is controlled. In contrast to mathematical models that extrapolate the dynamics of the studied process by a polynomial of degree n, the proposed model not only allows you to control the dynamics of the local process, but also to establish the type of function of thermal external influence.

3.2 The algorithm

The algorithm for controlling the temperature in a given space (region) is reduced to the following procedural steps: 1) generation of a set of control vectors $\vec{\varphi}$ and determination of the function of external thermal influence $W(t)$, at which the dynamics of temperature $\theta(t)$ does not exceed the specified limits (the authors solved this problem using the developed software in MathCAD [39] and Python [40]); 2) based on the obtained simulation results, a decision is made (for example, by an artificial intelligence system) to regulate the concentration of pollutant emissions into the atmosphere for a given region; 3) after the introduced corrections, the cycle of generation of control vectors and determination of the function of external thermal influence $W(t)$ is repeated until the dynamics of the variable $\theta(t)$ is stable within the selected limits.

The resulting system of differential equations is solved by the numerical Runge-Kutta method with a fixed step. The components of the control vector $\vec{\varphi}$ have a uniform distribution law.

3.3 The computational experiment and discussion

Zhytomyr (Ukraine) and the Zhytomyr region (see Fig.2) were chosen for the computational experiment.

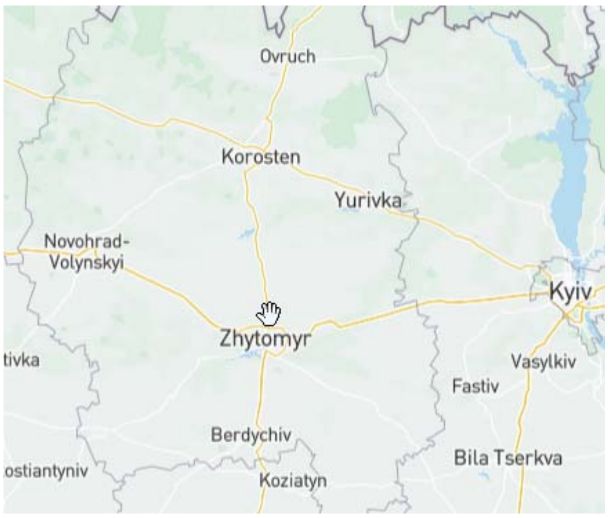

Fig. 2. Location of the research area: Zhytomyr (Ukraine), and Zhytomyr region.

Table 1 presents the statistical values of atmospheric air temperature provided by the meteorological complex (WMO Index 33325. Latitude: 50.270 °; longitude: 28.630 °) for December 2019.

After adapting the Lagrange equations [2] to the oscillatory system, we obtain the usual linear,

https://doi.org/10.1051/e3sconf/202128009011

inhomogeneous differential equation of the second order:

$$\frac{d^2\theta(t)}{dt^2} + A_0\frac{d\theta(t)}{dt} + A_1\theta(t) + A_2c_S = A_3W(t), \quad (1)$$

where A_0, A_1, A_2, A_3 - coefficients to be determined;

$W(t)$ - the function of external thermal influence, which is to be determined;

c_S is the average concentration of pollutants in the surface layer of the atmosphere in the study area for a fixed period.

Table 1. Atmospheric air average temperature values for December 2019, t ˚C.

1 decade	2 decade	3 decade
0.2	2.1	6.6
-1.3	2.2	5.6
-0.5	0.1	6.7
-0.4	0.5	7.8

0.7	6.5	1.1
4.2	8.4	0.1
3.6	6.7	-0.9
0.6	2.9	-3.6
**	**	2.0

Note that the components of the control vectors are different for each implementation of the dynamics of $\theta(t)$.

The dimension of the components of the control vectors and the functions of the external thermal influence, respectively:

$A_0 = [s^{-1}]$; $A_1 = [s^{-2}]$; $A_2 = [s^{-2}mg^{-1}m^3]$; $A_3 = [s^{-2}]$;

W(t) = [˚C].

The dimensionality of these coefficients can also be expressed in terms of units, namely [m] and [s]. That is, because of the spatial and temporal dimensions.

After the introduction of auxiliary functions, equation (1) will become a system of ordinary differential equations of the form:

$$\begin{cases} \frac{dy_2}{dt} = -A_0y_2 - A_1y_1 - A_2c_s + A_3W(t) \\ \frac{dy_1}{dt} = y_2 \end{cases}, \quad (2)$$

where $\theta(t) = y_1, \theta'(t) = y_2$ is the function of temperature change over time and the function of the rate of temperature change over time, respectively.

Fig. 3 presents the dynamics of statistical temperature values for December 2019, in accordance with the data in table 1.

For further processing of statistical data, we perform interpolation of statistical data by a power polynomial of the third-order by means of MathCAD.

The result of interpolation and the dynamics of statistical temperature data are presented in Fig. 4; time *t* – days of the month with a step of 0.31 days (total 101 steps).

The fragment of the matrix *Ys(t)*^{T} with the results of interpolation, is presented in Fig. 5

The next stage of modeling involves determining the composition of surface temperature that depends on the average monthly concentration of emissions of harmful substances into the atmosphere and the function of external thermal influence.

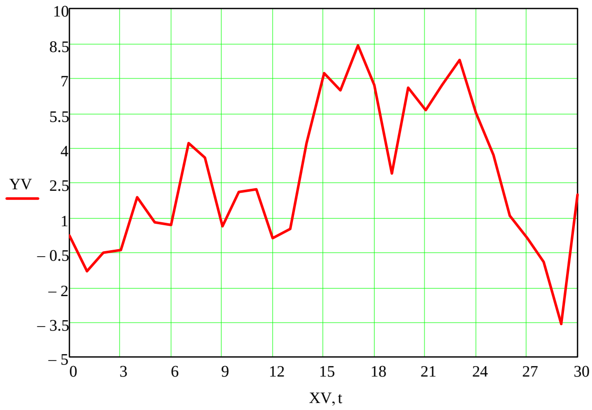

Fig. 3. Dynamics of *YV* statistical temperature values for December 2019, according to Table 1.

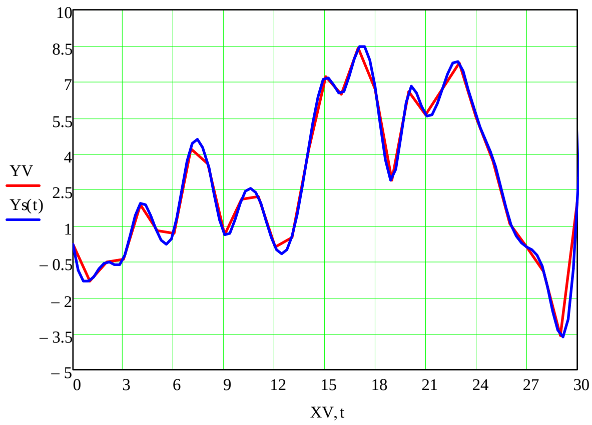

Fig. 4. The result of interpolation *Ys(t)* and the dynamics of *YV* statistical temperature values for December 2019.

0	0.2	-0.835	-1.292	-1.332	-1.115

Fig. 5. The fragment of the matrix *Ys(t)*^{T} with the results of interpolation.

Preliminarily, we establish the form of the slowly changing time function *P(t)*, which reflects the dynamics of the temperature component as a result of the combined influence of other factors (the main factor is seasonal solar activity).

The results obtained using the MathCAD system, allow us to represent the function *P(t)* as follows:

$$P(t) = 0{,}1737\text{-}0{,}2792t + 0{,}0679t^2 - 0{,}002t^3 \quad (3)$$

The graph of the slowly changing time function *P(t)* is presented in Fig. 6.

Some of the values of this function are represented by a fragment of the TREND^T matrix in Fig. 7.

Then the rapidly oscillating component of the BOOSK temperature, which is due to the anthropogenic factor of influence will have the form shown in Fig. 8.

Accordingly, the values of the rapidly oscillating component of the BOOSK temperature, which is due to the anthropogenic factor of influence, are represented by a fragment of the BOOSK matrix in Fig.9.

From the graph in Fig. 8, the upper and lower limits of the range of oscillations of the fast-oscillating temperature component BOOSK, which is due to anthropogenic factor, and requires the determination of many control vectors $\vec{\varphi}$, providing a set control range for each implementation of the oscillatory process described by equation (1).

Fig. 7. The fragment of the TREND^T matrix.

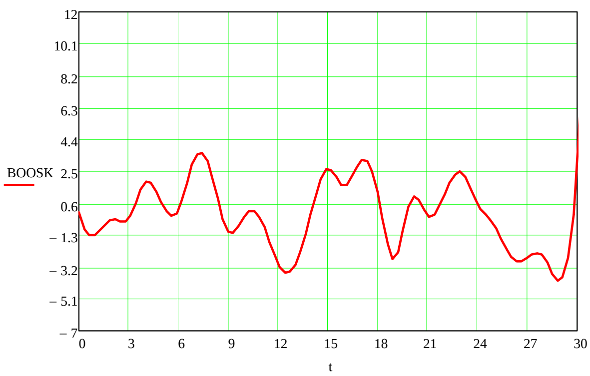

Fig. 8. The rapidly oscillating component of the BOOSK temperature, which is due to the anthropogenic factor of influence.

The final stage of modeling involves multiple implementations of the computational algorithm in MathCAD or Python. The experiment performed 901 iterations of the computational algorithm and obtained, respectively, 901 control vector $\vec{\varphi}$, which provides the dynamics of $\theta(t)$, i.e. the rapidly oscillating temperature component, which is due to an anthropogenic factor in a given range of fluctuations for a given month.

For example, three of the 901 calculated control vectors are shown in Table 2 (numbering begins with zero iteration).

Table 2. The values of the components of the control vectors $\vec{\varphi}$ for iterations № 0, № 110, № 700.

Control vector $\vec{\varphi}$ component	Iteration № 0	Iteration № 110	Iteration № 700
a_0	1.624×10^{-6}	1.298×10^{-6}	3.731×10^{-7}
a_1	2.986×10^{-6}	1.180×10^{-6}	4.574×10^{-6}
a_2	3.591×10^{-6}	1.343×10^{-6}	3.777×10^{-6}
a_3	2.967×10^{-6}	3.997×10^{-6}	5.086×10^{-7}

Fig. 9. The value of the rapidly oscillating component of the BOOSK temperature, which is due to the anthropogenic factor.

As noted above, the components of the set of control vectors $\vec{\varphi}$, ie a_0, a_1, a_2, a_3, are distributed according to the uniform law.

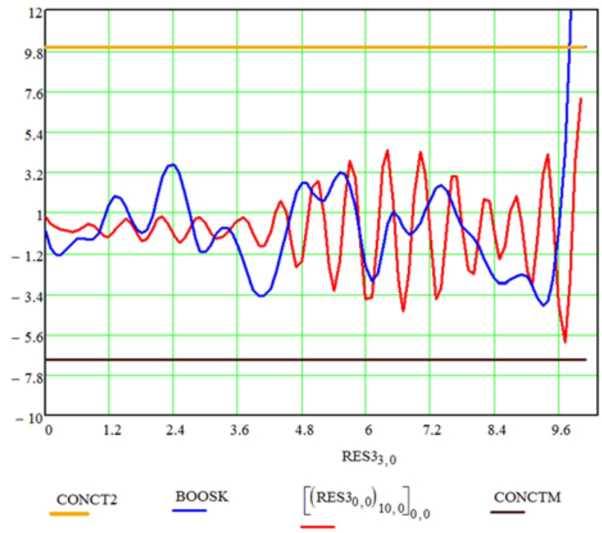

Fig. 10. The value of the rapidly oscillating component of the BOOSK temperature, which is due to the anthropogenic factor of influence. *CONCT2* - the upper limit of the range of temperature fluctuations, is + 10˚C. *CONCTM* - the lower limit of the range of temperature fluctuations is -7˚C. *RES3*$_{10.0}$ is a simulated implementation (as an example of iteration №10) of the dynamics of a function whose oscillation limits correspond to the set range. *RES3*$_{3.0}$ - days of the month with a step of 0.31 days.

In this case, according to the simulation results, the coefficients A_0, A_1, A_2, A_3 of the differential equation (1) will have the form: $A_0 = a_0 + 0{,}0005$; $A_1 = a_1 + 20{,}8$; $A_2 = a_2 + 0{,}4$; $A_3 = a_3 + 5{,}4$, and the function *W(t)* of external thermal influence for the controlled process of dynamics of $\theta(t)$ will have the form:

$$W(t) = (0{,}49t)^{2{,}1} Sin(10{,}2t) + 1{,}5tCos(9t\text{-}7) + 30 \quad (5)$$

The estimated average concentration c_S of pollutants in the surface layer of the atmosphere of the selected region is 400 mg/m^3.

Fig. 10 shows the dynamics of the rapidly oscillating temperature component, which is due to the anthropogenic factor of influence and is limited by the corresponding range of oscillations and simulates the results of the controlled process in the same range that was set.

The analysis of Fig. 10 shows that the set of solutions of equation (1) in general reproduces the dynamics of the rapidly oscillating temperature component, which is due to the anthropogenic factor of influence by emissions of pollutants into the surface layer of atmospheric air of the studied region.

For most of the period (31 days), the phase development of the simulated process is synchronous with the statistical. Partial amplitude discrepancies are observed.

In this case, a significant part of the statistical fluctuations is absorbed by the simulated process.

4 Conclusions

Based on the simulation results, it is proved that the set of solutions of equation (1) in general reproduces the dynamics of the rapidly oscillating temperature component, which is due to the anthropogenic factor by emissions of pollutants into the surface layer of atmospheric air of the studied region. The complexity of creating a perfect information system for managing global climate parameters leads to a narrowing of the task to the local level of a particular region.

For most of the period (31 days), the phase development of the simulated process is synchronous with the statistical. Partial amplitude discrepancies are observed.

In this case, a significant part of the statistical temperature fluctuations is absorbed by the simulated oscillatory process of the temperature regime.

Since the most important factor is to maintain a controlled temperature within the specified limits, the proposed mathematical model is adequate.

Unlike mathematical models that extrapolate the process, the proposed mathematical control model allows not only to determine the set of process control vectors but also to establish the form of the function of external thermal influence.

At small values of the component of the control vectors $\vec{\varphi}$, the process is easily controlled and there is a 901 process control vector within the specified limits. Therefore the criterion for the proven reliability of the obtained models is the power of the set of control vectors.

As the simulation results show, there are certain limits to the values of the control vector components and, as a consequence, the set of control vectors themselves can be significantly reduced when approaching the limit values of the control vector components.

That is, for example, from 901 computational iterations, only one control vector $\vec{\varphi}$ can correspond at fixed input parameters.

Since the simulation results are obtained solely through the use of information technology, the number of iterations of the computational algorithm is limited by hardware resources.

Thus, with the increase of computational steps in the Runge-Kutta method to 1000 and setting the number of iterations to more than 3000, there is a conflict between the computational algorithm and the hardware on which the computational experiment was conducted.

Further development of the proposed approach involves the use of artificial intelligence systems and the application to other similar geophysical phenomena of regional nature.

Abstract. In December 2019, the European Commission officially presented The European Green Deal, a new EU economic development program aimed at achieving climate neutrality on the European continent by 2050. Many previous global, European, and national programs also aim to reduce emissions of pollutants into the atmosphere. In this context, one of the ways to reduce emissions is the development of alternative energy sources (in particular the wider use of biofuel boilers) and increasing environmental tax rates. When choosing the optimal heating boilers, the practice of using the levelized cost of heating (LCOH) indicator is common. Environmental pollution tax (as a component of LCOH) is calculated for the three most common types of boilers (for Ukrainian boiler houses) with a capacity of 4.65 to 58 MW, burning natural gas, coal, and fuel oil, as well as low-power boilers burning organic and biofuels, for existing environmental tax rates, for projected increasing in 4 times (according to the bill) and subject to the introduction of minimum and maximum rates in EU countries. It is established that at the current environmental tax rates in Ukraine there are almost no economic incentives for the introduction of technologies to reduce the concentration of pollutants in emissions, but increasing environmental tax rates may change this situation. This, in turn, once again suggests that changing environmental tax rates can be an effective tool for achieving sustainable development goals.

1 Introduction

At the present stage of development, humanity uses so many resources that for the future in the near future we will lack the resources of our planet. Therefore, the global concept for solving this problem has become "sustainable development" - a development that meets the needs of the modern generation without harming future generations.

In a situation of stability, two competing pillars of sustainable development: the economic and the environmental one, are in the lead – as long as the basic needs of most people are satisfied [1].

Ukraine has made a number of commitments to protect the environment and reduce pollutant emissions [2, 3, 4]. The EU has adopted Directive 2015/2193 of the European Parliament and of the Council of 25 November 2015 on the limitation of emissions of certain pollutants into the air from medium combustion plants [5]. As this Directive is a supplement to Directive 2010/75 / EC (for installations over 50 MW), Ukrainian medium-capacity installations will have to prepare to comply with its standards.

Among budgetary and fiscal instruments for stimulating and ensuring sustainable development, environmental taxes occupy a prominent place.

In scientific publications and legislation of different countries, you can find different definitions of "environmental taxes". In particular, the legislation of Ukraine contains two such definitions that to some extent complement each other:

1) Environmental tax - a nationwide mandatory payment, which is based on the actual amount of emissions into the atmosphere, discharges of pollutants into water bodies, waste disposal, the actual amount of radioactive waste temporarily stored by their producers, the actual amount of generated radioactive waste and the actual the amount of radioactive waste accumulated before April 1, 2009 [6].

2) Environmental tax - a tax with a specific object of taxation, which clearly has a negative impact on the environment, or is aimed at taxing certain activities, goods or services so that the cost of environmental protection can be included in their price and/or guide producers and consumers for activities that are best for the environment [7].

Many countries around the world have long used this powerful toolkit, many are just beginning, but common to most countries is that legislation in this area is constantly improving, including changes in environmental tax rates.

* Corresponding author: st_v_v@hotmail.com

Ukraine is no exception. As of December 2020, there are 3 different bills in the Parliament of Ukraine, about increasing the rates of environmental tax in Ukraine.

Given that one of the industries that are significantly affected by environmental tax rates is heat, it is advisable to conduct a study on the effects of changes in environmental tax rates on economic and environmental pillars of sustainable development.

2 Literature review

This article is a continuation of previous research by the authors [8, 9]. A lot of work has been devoted to the study of the impact of environmental taxes on sustainable development goals. Consider the main ones for 2018-2020

The study [10] employs the GTAP-E-Power model with additional improvements to include non-CO 2 emissions to examine the impacts of such a policy on the Vietnamese economy. Authors show, that higher tax on coal would foster the extension of renewable energy sectors faster than the impacts resulted from increasing tax on petroleum products. The increased demands by the private sector for electricity generated from renewable sources signal the potential for sustainable development of the renewable electricity generation sectors in Vietnam.

In paper [11] authors consider from an environmental policy-maker perspective, how carbon reduction policies impact the economic competitiveness of the manufacturing sector and note that the obtained results offer support to both environmental policy-makers and corporate production and sustainability managers to determine whether it is technically feasible and profitable to replace traditional scheduling strategies with environmentally friendly scheduling strategies.

Article [12] study how new sustainable business models in the energy sector work, and investigate their risk profile, especially concerning the risk of regulatory changes.

Paper [13] investigates the determinants of environmental tax revenue.

Findings [14] clearly indicate that (a) the proportion of tourism energy consumption to national energy consumption in China will increase over time, (b) the impacts of a carbon tax on China's tourism fossil energy consumption, electricity consumption, and energy intensity will become increasingly weak, (c) the impacts of a carbon tax on electricity use are greater than the impacts on fossil fuel consumption, and (d) the impacts of different carbon taxes on the levels of energy consumption and energy intensity will vary to a significant degree between the different tourism sectors.

The study [15] introduced an original interdisciplinary assessment model of performance-based contracting for SO_2 emission control in Chinese coal power plants that involves key environmental policies including command-and-control regulations, market-based approaches, and administrative measures, as well as technology, market, and capital variables (Fig. 1).

Paper [16] describes a new carbon price mechanism with full emission coverage which developed within the framework of a global computable general equilibrium model (GTAP-E-PowerS) to enhance the capacity and accuracy for climate change and energy policy assessment. The results indicate that South Africa is likely to move to low carbon and sustainable economy with such a policy.

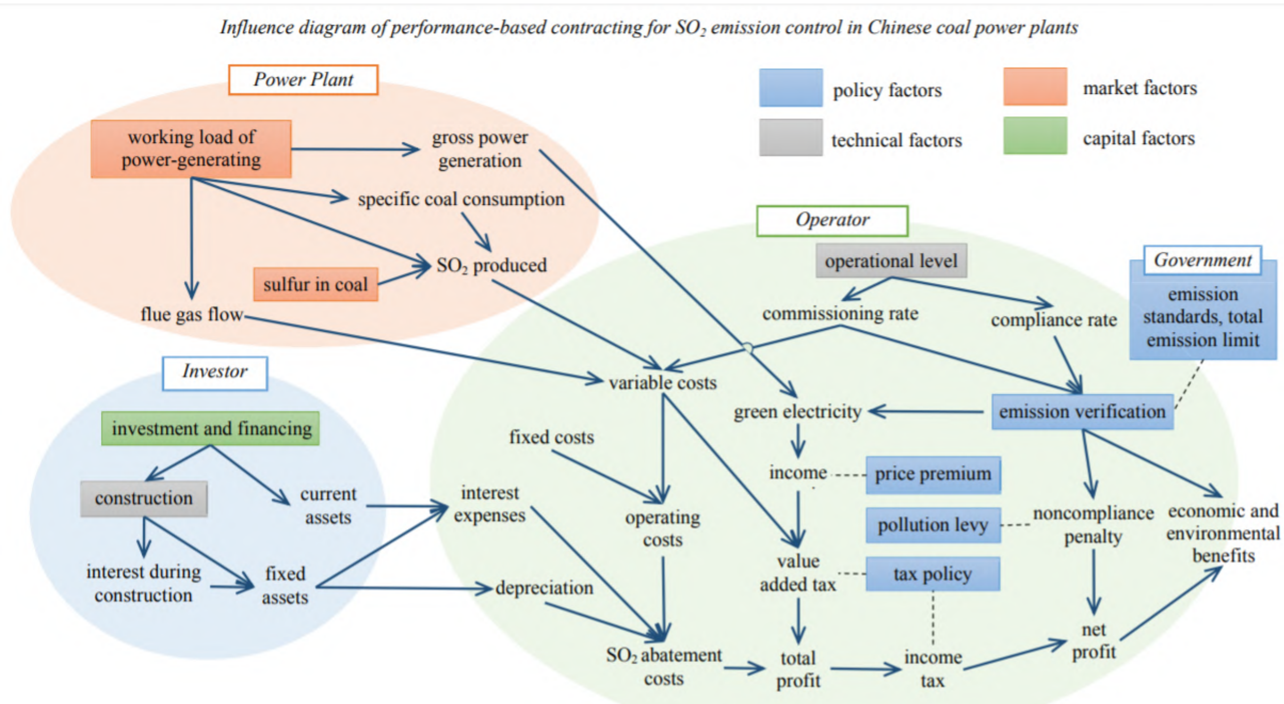

Fig. 1. Stakeholders, uncertain factors, and interactions in performance-based contracting for SO2 emission control in Chinese coal power plants. Arrows indicate the dependence; dashed lines indicate the environmental policy boundaries [15].

 https://doi.org/10.1051/e3sconf/202128009012

Article [17] shows, that the required carbon tax begins from $ 5.29/ton in 2020 and grows on average by 3.5% reaching up to $ 35.83 per ton carbon towards the year 2075.

In paper [18] is writing, that towards the reduction of greenhouse gas emissions, a carbon tax has been already introduced in 40 countries, but owing to different carbon prices among countries, there are potential risks of carbon leakage, where manufacturers transfer production operations to countries with lower taxes to pursue lower costs.

The paper [19] deals with the greening of tax systems in the European Union (EU) and reviews the achievements of the Baltic States in relation to greening their tax systems and implementing the sustainable energy development goals set by the EU's energy policies.

The Levelized cost of energy (LCOE) and its analog for heating - Levelized cost of heating (LCOH) are the widespread indicators, which is often used for cost comparisons for energy and heating generation [20-23 and other].

Paper [20] shows, that the application of the “traditional” LCOE formula has some problems, therefore authors present a modification to the traditional LCOE formula, which considers energy price rise and thus allows more accurate LCOE calculations.

The study [22] presents a new approach and methodology, which developed which uses the United Kingdom “audited” data, published in company accounts, that has been obtained from Companies House, to determine more accurate LCOE estimates.

The paper [23] provides the techno-economic comparative analysis of eight Biomass Integrated Gasification Combined Cycle (BIGCC) system designs that include the technology options of the biomass gasification, the power generation, and the CO_2 emission control. Results show that the LCOE of these systems is ranged from 0.131 $/kWh to 0.259 $/kWh.

3 Methods

The initial data for calculating emission taxes are the annual consumption of a particular type of fuel by the boiler plant (determined by the thermal capacity and efficiency of the boiler plant, its operating time, and installed capacity utilization factor), fuel calorific value, pollutant emission factors and eco tax rates.

Table 1 shows the emission factors of pollutants during the combustion of different fuels without the use of technologies to reduce emissions of pollutants.

Table 2 shows the tax rates for air emissions of certain pollutants by stationary sources of pollution, which include boilers of heating boilers, according to Articles 243.1 and 243.4 of the Tax Code of Ukraine [6].

In November 2019, 3 bills (draft laws) on increasing environmental tax rates were submitted to the Verkhovna Rada. The bill on Amendments to the Tax Code of Ukraine to increase environmental tax rates and implement European principles of modernization of Ukrainian industry 2367-1 of November 18, 2019, proposes to increase tax rates for air emissions from 2030. According to this bill the growth rate will be gradual: from 01 January 2021 to December 31, 2022, inclusive, tax rates are 75% of the rates provided by the bill, in 2023-2024 - 80%, in 2025-2026 - 85%, in 2027-2029 - 90%.

Bill 2367 of November 1, 2019 proposes to increase tax rates by 4 times (Table 2).

In EU countries, tax rates differ dozens of times, in Poland some of the lowest in the EU, in Sweden - the highest (Table 3), the rate - 34.64 UAH/EUR.

Sweden levies the highest carbon tax rate at €112.08 (US$ 132.17) per ton of carbon emissions, followed by Switzerland (€83.17, $98.08) and Finland (€62.00, $73.11). You’ll find the lowest carbon tax rates in Poland (€0.07, $0.08), Ukraine (€0.33, $0.39), and Estonia (€2.00, $2.36).

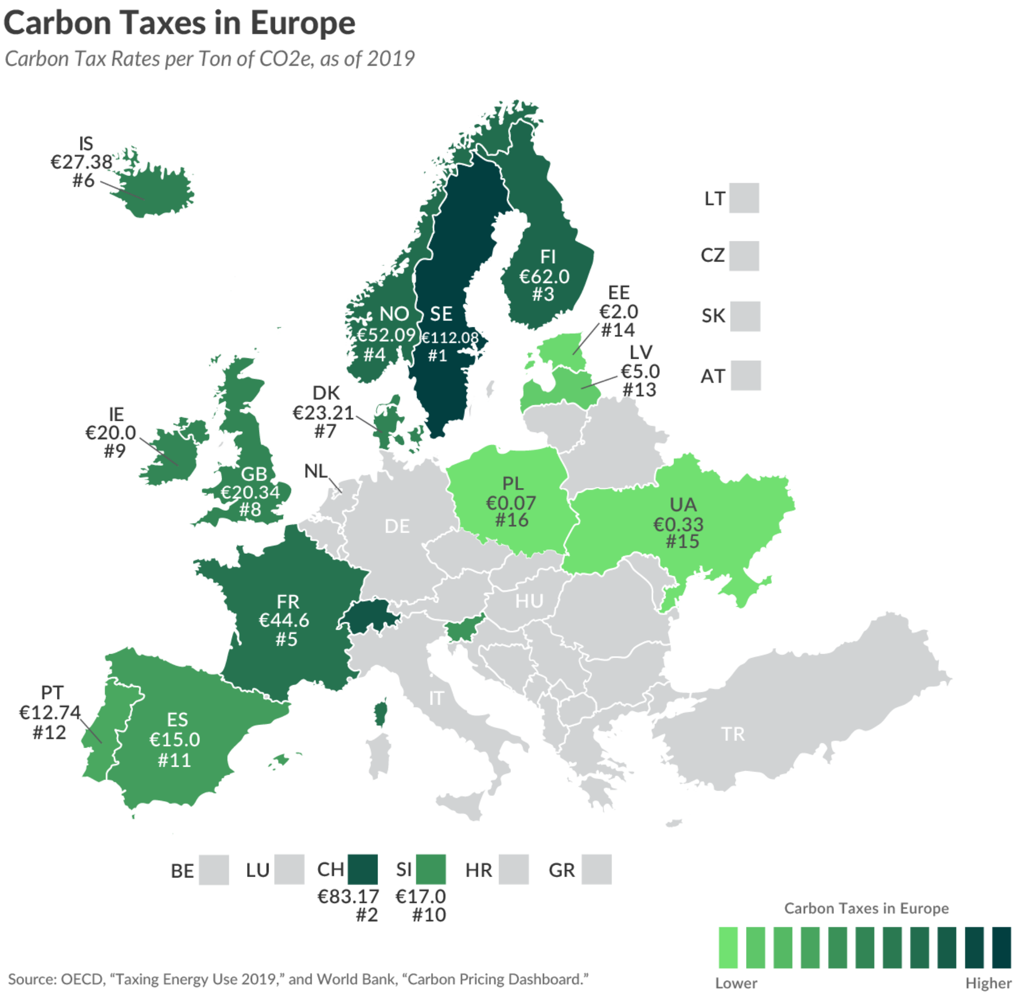

Fig. 2. Carbon Taxes in Europe [30].

It is proposed to calculate the levelized cost of heat taking into account the environmental tax, by the expression:

$$LCOH_{T_{eco}} = \frac{\sum_{t=1}^{N} \frac{I_t + M_t + F_t + T_t^{eco}}{(1+r)^t}}{\sum_{t=1}^{N} \frac{H_t}{(1+r)^t}} \quad (1)$$

where:
I_t is investment expenditures in year t
M_t is operations and maintenance expenditures in year t
F_t is fuel expenditures in year t
H_t is energy (heat) generation in year t
r is discount rate
N is lifetime of the technology
T_t^{eco} is environmental tax.

Thus, the change in LCOH due to the environmental tax is determined by the expression:

$$\Delta LCOH_{eco\ tax} = LCOH_{T_{eco}} - LCOH \quad (2)$$

Taxation of pollutant emissions in Ukraine is carried out in accordance with Section VIII of the Tax Code of Ukraine [6].

The expenditures included in the formula for determining the levelized cost of heat are divided into permanent (administrative) and variable (operational) costs.

4 Results and discussion

For the study, the authors used data from [9, 31], which was calculated the LCOH and the contribution of environmental tax in LCOH for three types of boilers with a capacity of 4.65 to 58 MW, burning natural gas, coal and fuel oil, which the most common for boiler houses of Ukraine [9], and for boilers on different types of biofuels with a capacity of 1 MW [31].

$\Delta LCOH_{eco\ tax}$ is calculated to an increase in eco tax rates by 50% and 4 times (according to Ukrainian bills) and the eco tax rates in Poland (one of the lowest in the EU) and Sweden (highest in the EU).

The contribution of the environmental tax to the LCOH indicator depending on the different rates of the environmental tax, which were given in tables 2 and 3, are presented in the table. 4

Table 4. $\Delta LCOH_{eco\ tax}$ at eco tax rates of Ukraine (current and project), Poland and Sweden for boilers on different fuels

Boiler, its power	Fuel type	LCOH without eco tax	$\Delta LCOH_{eco\ tax}$					
			Ukraine	Ukraine, Bill 2367-1 of November 18, 2019		Ukraine, Bill 2367 of November 1, 2019	Poland	Sweden
				from 2021	from 2030

KV-2.0, 2 MW	natural gas	1090.08	3.40	3.49	3.75	13.61	1.88	1015.15
ARS 1000, 1 MW	anthracite	720.45	38.61	42.80	55.40	154.42	93.49	2090.03
	wood	529.64	7.30	7.48	7.99	29.22	5.17	2313.97
	wood chips	687.35	6.59	6.75	7.26	26.34	4.95	2041.22
	natural gas	1125.28	3.79	3.90	4.20	15.18	2.16	1167.51
ARS 1000 BM, 0.98 MW	wood pellets	634.14	5.58	5.71	6.09	22.32	3.32	1774.06
	wood	492.70	6.71	6.87	7.34	26.84	4.75	2125.62
Gefest Profi-P 1000, 1 MW	straw briquettes	521.04	7.03	7.34	8.25	28.12	5.63	1793.16
	wood pellets	637.96	5.58	5.71	6.09	22.32	3.32	1774.06
	sunflower husk pellets	379.18	7.75	8.15	9.33	31.00	6.84	1798.75

In case of eco tax rates increasing for emissions of all pollutants in 4 times, the mentioned component of the LCOH will increase for natural gas boilers - from 3.40 to 13.34 UAH/Gcal, for fuel oil boilers will increase from 10 to 40 UAH/Gcal, for coal-fired boilers - from almost 40 to 150 UAH/Gcal.

For biofuel boilers the growth will be from 6-7 to 22-28 UAH/Gcal, namely from 5.58 to 22.32 UAH/Gcal for wood pellets boilers, from 7.75 to 31.00 UAH/Gcal for sunflower husk pellets boilers.

At current eco tax rates $\Delta LCOH_{eco\ tax}$ is from 0.3% for gas boilers to 5.3% LCOH, for biofuel boilers from 0.9% (wood pellets) to 2.0% (sunflower husk pellets). If the eco tax rates are increased in 4 times, it will be from 1.2% (gas boilers) to 21% LCOH (coal boilers).

Poland has the lowest environmental tax rates in EU, so the environmental component of LCOH (taxes), for their case will increase for fuel oil boilers by 70%; for coal-fired boilers it will more than double, and for natural gas boilers it will generally halve (due to a lower CO_2 tax rate).

If the highest rates in the EU (Sweden) are used, the environmental component LCOH (tax) for coal-fired boilers will be in 2.6 times larger as the investment, operating and fuel costs component, for gas boilers, the environmental component will be 95%, and for fuel oil boilers - 105%, for biofuel boilers – will be in 2.8-4.7 times larger. The largest contribution is the tax on CO_2 emissions, the tax rate of which is 388 times higher than in Ukraine. The environmental component LCOH (tax) under these conditions is tens of thousands of times higher than at existing tax rates in Ukraine.

With the introduction of Sweden tax rates, the cheapest will be heat from high-power gas boilers - 2040 UAH/Gcal, heat from boilers burning some types of biofuels (2728, 2843 UAH/Gcal) becomes more expensive even than heat from fuel oil and coal boilers (2570-2638 UAH/Gcal). This will stimulate further introduction and use of gas boilers, which contradicts the goal of increasing the share of local biofuels.

In many countries around the world, including EU countries, biofuels are considered CO_2 neutral and no CO_2 tax is levied. Subject to the introduction of Swedish tax-free rates for CO_2 emissions, the environmental component of LCOH (taxes) for biofuel boilers will range from 7.2 to 16.1 UAH/Gcal.

5 Conclusions

In December 2019, the European Commission officially presented The European Green Deal, a new EU economic development program aimed at achieving climate neutrality on the European continent by 2050. Many previous global, European, and national programs also aim to reduce emissions of pollutants into the atmosphere. In this context, one of the directions is the development of alternative energy sources (in particular the wider use of biofuel boilers) on the one hand and increasing environmental tax rates on the other (which will lead to reduced emissions).

Many leading countries in the world have long used changes in environmental tax rates as one of the tools to achieve sustainable development goals. Ukraine is also trying to join them. As of December 2020, there are 3 different bills in the Parliament of Ukraine, the adoption of which will change the rates of environmental tax in Ukraine, sometimes in times. However, as of December 30, 2020, none of these bills have been adopted.

It is established that at the current environmental tax rates in Ukraine there are almost no economic incentives for the introduction of technologies to reduce the concentration of pollutants in emissions, but increasing environmental tax rates may change this situation, and environmental tax rates will be an effective tool for achieving sustainable development goals in Ukraine.

The authors calculated the environmental component of LCOH (taxes) at eco-tax rates of Ukraine (current and project), Poland, and Sweden for boilers on different fuels. If the highest rates in the EU (Sweden) are used, the environmental component LCOH (tax) for all fuel type boilers will be equal to the investment, operating and fuel costs component for natural gas and fuel oil boilers, in 2.6-4.7 times larger for coal and biofuel boilers. The cheapest will be heat from high-power gas boilers - 2040 UAH/Gcal, heat from boilers burning some types of biofuels (2728, 2843 UAH/Gcal) becomes more expensive even than heat from fuel oil and coal boilers (2570-2638 UAH/Gcal). This will stimulate further introduction and use of gas boilers, which contradicts the goal of increasing the share of local biofuels.

Only increasing the rates of the eco-tax without its smart administration (for example, benefits, refund of part of the funds for the eco-modernization, etc.) will not ensure the effective use of these tools to achieve sustainable development goals.

Abstract. COVID-19 pandemic is an emergency that spread across the planet. It threatens lives and health of the population, with many dead and injured. Also, during pandemic there was (and continues to be) a violation of normal living conditions, significant material damage to economies of different countries. Quarantine restrictions affected social, educational, cultural and spiritual spheres of society. There is an urgent threat to operation of critical infrastructure as the pandemic led to large numbers of hospitalized or self-isolated people and being treated at home. At present, the operation of critical infrastructure, and in particular nuclear power plants, is strategically important for the proper functioning of any country. Also, the research describes causes of emergencies at nuclear power plants and identifies another factor - the mass disease of NPP personnel or their relatives on COVID-19. It is determined that timely detection and appropriate work to restore mental health during the pandemic is no less important area of work along with providing medical care to population. Stress associated with uncertainty, threat to health, can have negative consequences for well-being and mental health of workers. Depression, emotional exhaustion, anxiety, irritability, suicidal thoughts, etc. can also be consequences. Socio-psychological support especially for critical infrastructure workers is important to promote mental health during COVID-19 pandemic. Recommendations for socio-psychological support of NPP personnel were developed. Specialized mobile applications are described as convenient and economical way for primary psychological care.

1 Introduction

COVID-19 spread around the world. It is not only health problem, but it also affects the world economy and the environment in various ways. Although COVID-19 causes serious damage to society but environment state is improved as pollution decreased significantly. COVID-19 imposed restrictions on the movement of people and vehicles in various countries and suspended some industrial activities. Thus, emissions of greenhouse gases, nitrogen dioxide, carbon, etc. decreased. However, COVID-19 also has negative consequences for environment due to large amount of household and medical waste [1, 2, 3].

COVID-19 and the quarantine restrictions caused by it became an emergency situation that significantly affected well-being of people, families, communities. People experience such situations in different ways, someone without visible violation of ability to function at work or in a close relationship. That is, such people recover quickly, using their own strength. Others need only basic support to improve their well-being. And in the third, there are mental health problems (or the same problems that existed before) that require specialized psychological support. Therefore, response to emergencies is significantly different in each case, as each person experience the same event differently and has different resources and opportunities to recover [4].

Indeed, the pandemic is a challenge not only to physical health but also to mental health. The Secretary-General of the United Nations called on governments to address mental health needs of the coronavirus pandemic immediately, warning that COVID-19 could provoke crisis in this area. An important area for strengthening of mental health strategy during COVID-19 outbreak is psychological support of population, especially health

* Corresponding author: anna13.00.10@gmail.com

workers. Stress associated with uncertainty, threat to health, can have negative consequences for well-being and mental health of employees, and can result in depression, emotional exhaustion, and anxiety. Therefore, recovery of mental health and psychosocial aspects during outbreak of COVID-19 are extremely relevant and require special research [5].

COVID-19 disease made many significant changes in activities of various enterprises and organizations, many employees were transferred to remote mode using digital technologies. However, there are enterprises, especially of critical infrastructure (nuclear power plants, thermal power plants, chemical facilities, etc.), where it is impossible to perform official duties remotely and you need to be in the workplace. Critical infrastructure facilities can include enterprises, institutions and organizations, regardless of ownership, which: operate and provide services in the energy sector, chemical, transport, information and communication technologies, electronic communications, banking and financial sectors; provide services in areas of life support of the population, in particular in areas of centralized water supply, sewerage, electricity and gas supply, food production, agriculture, health care; communal, emergency and rescue services, emergency services; included in the list of enterprises of strategic importance for the economy and safety of the state; objects of potentially dangerous technologies and productions.

Today in Ukraine there is developed nuclear energy industry. Its operation is provided by 4 operating nuclear power plants (NPPs): Zaporizhzhya NPP, Rivne NPP, South-Ukraine NPP and Khmelnytska NPP. They are objects of increased danger [6, 7], and therefore issue of their safe operation, civil protection of population and environment on the territory of the station is always relevant.

In Ukraine, NPPs consistently provide more than half of electricity production, which is important for economic and social development of the country and compliance with international obligations. In [6] it is noted that experience of NPP operation shows that causes of accidents and incidents are somehow related to behavior of people (human factor), namely - with their attitude to safety problems. Therefore, the focus of NPP management is, first of all, human resources, style and management methods. An important issue for the NNEGC “Energoatom” is to maintain health of its employees at the appropriate level and timely detection of diseases. This is especially important given that work of nuclear workers is associated with increased hazards, including radiation. To preserve the health and efficiency of NNEGC “Energoatom” NPP personnel, conducts constant explanatory work among the personnel about vital need to take care of one's own health, to objectively assess condition of well-being, timely treatment by doctor. In the NNEGC “Energoatom” units where high-risk work is performed, mechanisms of psychophysiological examination of employees are used. Psychophysiological examination is carried out in order to: ensure safety, reliability and efficiency of NPP operation through optimization of personnel; reduction of labor losses and accident prevention; selection of persons who, by the state of professionally important psychophysiological qualities, are able to master the profession and perform their duties effectively; working life of staff.

Monitoring of the psychophysiological condition of NPP employees is carried out during initial and periodic medical examinations. It does not reveal current situation of possible accumulation of fatigue and distress. Also, psychological climate controlin the teams is rare. Its constant implementation (taking into account recommendations of experts in psychophysiological laboratories of nuclear industry) will predict occurrence and influence of distress factors, as emphasized in the publication [7].

In 2020 for the first time unprecedented phenomenon of voluntary social isolation emerged as a way to effectively combat spread of COVID-19 virus. Following recommendations of the World Health Organization the most governments introduced quarantine measures. They severely restricted movement of citizens and effectively led to their self-isolation. Public, social, professional, scientific, religious life of people changed emphasis towards online presence. An integral part of the current quarantine is the Internet, mobile communications, Smart-phone, social networks and other digital technologies [5].

Therefore, number of problems need new understanding and research: professional activities of staff during the pandemic; human mental health; training of workers during the pandemic; social and psychological support of population and especially staff of critical infrastructure during the pandemic, etc.

2 Analysis of previous publications

Various aspects of software and hardware development for impact assessing of potentially dangerous objects on the environment are described in [8-30]. Features of prevention, occurrence and liquidation of emergencies, in particular at NPPs are considered in publications [7-43]. Provision of psychological support and assistance to victims in emergencies is described in the researches [4, 5, 44-49]. The use of digital technologies for psychological support of personality is considered in publications [50-55]. However, it is important to study impact of COVID-19 on emergencies at Ukrainian NPPs, psycho-traumatization of population during the pandemic and the search for tools and recommendations for socio-psychological support of population and NPP personnel.

The research aim – is to investigate new challenges of emergencies risk increasing at Ukrainian NPPs as result of the human factor during COVID-19 pandemic and to develop recommendations for their minimization.

3 The research results

3.1 Pandemic caused by COVID-19 as emergency

Every day there are various emergencies in different parts of the world: floods, earthquakes, landslides, hurricanes, dust storms, accidents, catastrophes and other natural disasters. In the beginning of 2020 the World Health Organization declared health emergency of international importance. And a pandemic was declared in early March. The pandemic caused by COVID-19 and quarantine restrictions also caused global socio-economic problems.

In the scientific literature [4] "emergencies" are understood as events that go beyond the ordinary life of man and pose a threat to their physical and mental integrity, lead to destruction of social structure of communities and social order. Such situations usually arise as result of accidents, catastrophes, natural disasters, terrorist acts, armed conflicts, epidemics, and others. Emergencies can spread to different scales in covered area, number of victims and so on. The Civil Protection Code of Ukraine [56] states that "an emergency situation is a situation on separate territory or a water body which is characterized by violation of normal living conditions caused by catastrophe, accident, fire, natural disaster, epidemic, epizootic, epiphytosis, use of means of destruction or other dangerous event that led (can lead) to threat to life or health of the population, large number of dead and injured, significant material damage, as well as impossibility of living in such territory or object, conducting economic activity on it. Also, victims of an emergency are people whose health was damaged in result of emergency.

In [56, 57] the *classification of emergencies* is given: 1) emergencies are classified by the nature of origin, degree of distribution, amount of human losses and material damage; 2) depending on nature of events origin types of emergencies are determined: (man-made nature; natural nature; social; military); 3) the following levels of emergency situations are determined depending on the consequences extent caused by emergency situation, amount of technical and material resources necessary for their elimination: state; regional; local; object; 4) classification of emergencies according to their levels is established by the Cabinet of Ministers of Ukraine [56].

The study [1] noted that level of air pollution is one of the important indicators that affects the transmission of COVID-19 and mortality. Therefore, COVID-19 can affect environmental factors and vice versa. Critical review of research of relationship between COVID-19 and the environment can formulate a current state of knowledge and guidance for further research. Critical analysis of scientific publications was conducted and 57 articles on interaction between COVID-19 and the environment were selected. Four research clusters were identified (Fig. 1): 1) COVID-19 and environmental degradation; 2) COVID-19 and air pollution, 3) COVID-19 and climate/metrological factors; 4) COVID-19 and temperature. The impact of COVID-19 on the environment and impact of environmental indicators on transmission of COVID-19 are considered. It is concluded that COVID-19 pandemic improved environment quality. During pandemic and quarantine restrictions imposed by the governments of different countries led to significant reduction in environmental pollution and improved environmental quality. There is a sharp reduction in carbon emissions, reduced air pollution, reduced noise pollution and beach pollution. Various environmental factors contributed to both spread and reduction of COVID-19 transmission [1].

Collective work [58] emphasizes that COVID-19 pandemic and its consequences can be rehearsal for fight against climate change in the future. The pros and cons of COVID-19 in terms of environmental impact were identified: improving air quality, improving surface water quality, reducing noise pollution and greenhouse gas emissions.

Humans, their life, health and safety are recognized in Ukraine as the highest social value. Geographical environment is the natural basis of her life [59, 60]. Mankind has extensive knowledge in the fields of geography, physics, chemistry, biology, and others, actively uses them in social production at the present stage of its development. At the same time it still remains dependent on natural manifestations of the nature forces. Processes that are beyond human control and are related to the life cycle of our planet and influence of external factors can cause emergencies of various kinds. Danger to humanity can be hidden in man-made objects and processes in addition to forces of natural origin: enterprises of various sectors of economy and technological processes, critical infrastructure, defense facilities, etc. Nuclear energy, use of electricity and heat, circulation of hazardous substances cause potential danger of emergencies. They are commonly called man-made [61].

Large proportion of industrial enterprises is potentially dangerous objects associated with the production, storage, transportation and processing of hazardous substances on the territory of Ukraine. Man-made emergencies risk at such enterprises is extremely high as the level of equipment wear in most enterprises is approaching critical. Accidents at such facilities are usually accompanied by environment pollution with toxic substances as well as fires and explosions [59].

People affected by emergencies can need medical care, psychological, material, legal assistance, social and information services, etc. [4]. Emergencies can lead to human casualties, damage to human health, significant material loss and disruption to people's living conditions. They can cause mental and psychological trauma to victims or their relatives and friends.

3.2 Causes of emergencies at nuclear power plants: domestic and foreign experience

Scientists in the publication [7] emphasizes that various negative circumstances (infringement processes, safety and mode of operation, natural disasters, technological accidents and incidents of sabotage terrorist purposes, fighting, etc.) at the plant can lead to different emergencies that pose a significant risk to environment, health of personnel and surrounding areas population. It is determined the nature of the action, the scale of destruction of buildings, the size of the material and economic losses by carrying out an analysis of emergency situation on the threat to human life. The most dangerous are emergencies that cause radioactive and chemical pollution. Confirmation of this are tragic experience of accidents at the Three Mile Island NPP (USA, 1979), Chornobyl (Ukraine, 1986), Fukushima-1 (Japan, 2011). Such emergencies can lead to significant radioactive contamination, cause significant damage to public health, natural and agroecological systems, etc.

In Ukraine, various normative documents emphasize importance of population protecting from emergencies.

The source [56] states that "civil protection is a function of the state aimed at protecting population, territories, environment and property from emergencies by preventing such situations, eliminating their consequences and providing assistance to victims in peacetime and in special periods".

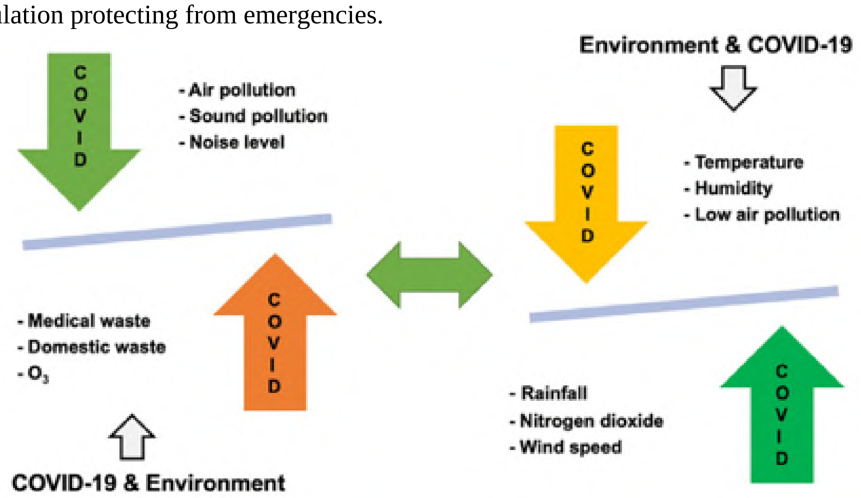

Fig. 1. Interaction of COVID-19 and environment (4 research clusters) [1].

Nuclear safety is ensured by consistent implementation of 5 defense levels in depth strategy. Implementation of measures last defense in depth - the fifth and, partly, in the fourth - in support of measures designed accident management. It is provided by system of emergency preparedness and response NNEGC "Energoatom" in accident and emergency at the plant. Important state task is to mitigate or prevent action of various factors and minimize accidents risk at nuclear power plants, as these stations are economically justified and necessary for normal development of industry, but only if the technical level of nuclear and radiation safety of nuclear power plants is provided [7].

Currently, Ukraine's nuclear energy sector is supplied by 4 operating nuclear power plants: Zaporizhzhya, Rivne, Khmelnytska and South-Ukraine. Analysis of violations at NPPs is carried out in accordance with industry standard "ND 306.2.100-2004 - Regulations on procedure for investigation and accounting of violations in operation of nuclear power plants". It is developed in accordance with international requirements. Work of investigating and accounting for violations in operation of nuclear power plants is very important for safety. This is an element of safety culture. Investigation and accounting of NPP operational events are part of professional culture of nuclear industry with its first steps [62].

Operation of NPPs of Ukraine is carried out in accordance with legal requirements. Their main purposes are: protection of health from possible damage associated with irradiation with sources of ionizing radiation; safe operation of NPPs; environment protection. NPP meets safety requirements when its radiation exposure does not exceed the limits prescribed dose irradiation plant personnel and the public, as well regulations on gas-aerosol emissions and liquid discharges, content of radioactive substances in the environment. NNEGC "Energoatom", NPPs and other separate units within it fully comply with requirements of nuclear and civil protection legislation - in terms of their obligations and responsibilities for development and implementation of emergency preparedness and response measures, civil protection [43].

According to experts from the World Association of NPP Operators, NNEGC "Energoatom" occupies a worthy place in the global nuclear community in terms of nuclear safety and organization of safety culture. Each Ukrainian NPP has examples of positive practices on safety culture. It corresponds to the best world experience, gained during implementation of international projects, etc. The company supports and encourages formation of safety culture among its employees and employees of other organizations that perform work for the NPP. The Council of nuclear safety culture was created in order to determine goals, objectives, optimize implementation of safety culture principles in the operation of Ukrainian NPPs exchange experience, assess the current level of safety culture at NPPs, as well as to review, approve and further monitor the implementation of specific actions of the NPP and the Company as a whole [6].

National emergency prevention organizations, together with research institutes, conduct joint research to increase Europe's preparedness to respond any radiation pollution caused by an emergency or long-term pollution, as part of the joint European EURANOS project. Threat of potentially dangerous situations remains even taking into account improvement of emergency preparedness and response systems emergency situations, the use of automated systems for monitoring technological parameters and the radiation situation at nuclear power plants [7].

Causes of emergencies at nuclear power plants [7]: violation of technological processes; violation of safety and operating conditions; natural phenomena and man-made accidents and incidents; fighting; sabotage for terrorist purposes. Small amount of news and events that take place at the nuclear fuel cycle facilities are posted on the site [63]. Also, more detailed information on nuclear and radiation events can be found in the IAEA Unified System for Information Exchange in Incidents and Emergencies.

Based on the analysis of scientific sources and specialized sites [7, 41, 43, 63] we will describe the occurred incidents at various nuclear power plants over the past few years. They were officially reported to the public.

1) in December 2015 at the Leningrad NPP (Russia) there was an accident at the second power unit. Pipeline burst in the turbine hall and the radioactive steam in it filled the room and spread outside the power plant. Cloud of radioactive release reached the territories of Estonia and Finland;

2) in January 2017 power supply of substation and the first power unit of the Armenian NPP was interrupted as result of accident on high-voltage power line. The accident cause on the power line was ice. It was formed as a result of frosty weather. There were no power outages;

3) in January 2017 in Japan a construction crane used for repair work at the Takahama NPP fell from strong wind on the second power unit and the spent nuclear fuel pool. The crane damaged part of outer wall and roof of the pool;

4) in February 2017 as a result of an explosion at the French nuclear power plant Flamanville, five workers were poisoned. The reactor reacted in operation was immediately shut down, although the explosion occurred outside the scope of nuclear fuel facilities;

5) in July 2018 in the city of Chernavode (Romania) there was an automatic disconnection from the National Energy System of the first power unit of the Romanian NPP. However, this sudden shutdown of the reactor did not affect the population, the station staff and the environment, and was most likely caused by an erroneous signal;

6) in July 2018 in Belgium at the Tihange NPP due electromechanical damage there was an emergency shutdown of the second reactor. The failure occurred due to problems with connection to the high-voltage network;

7) in September 2018 in Japan on the island of Hokkaido there was an emergency due to an earthquake. There was failure in operation of the main energy source that feeds pools cooling system with used nuclear fuel at the Tomari NPP. There was no radiation leakage;

8) in October 2018 in the west of Finland the first power unit of the Olkiluoto NPP of the company-operator Teollisuuden voima was disconnected due to turbine failure. It caused disconnection from the Finnish state grid. This incident did not affect nuclear safety of the facility.

9) in April 2019 a fire broke out at Rivne NPP in the evening. Due to damage to the 7AT communication transformer with its subsequent combustion the first 330 kV bus system was disconnected and the №3 power unit was disconnected accordingly. Rescuers put out the fire around 10 p.m. This event was classified as “zero” according to the international scale of events at the INES nuclear facilities;

10) in January 2020 an emergency situation occurred at the Ikata NPP (Japan). At the third NPP power unit, one of the 48 control cassettes was accidentally removed during withdrawal of fuel assemblies and no radiation leakage occurred.

The source of data on dangerous events that occurred at Ukrainian NPPs are reports on the investigation of violations in their work and the information system “Violations in the work of nuclear power plants”. Information reports on violations in the operation of Ukrainian NPPs during 2020 are presented on the website of the State Scientific Technical Center for Nuclear and Radiation Safety [41]. Fig. 2 shows number of violations in operation of Ukrainian NPPs during 2005-2019. Distribution of violations in operation of NPPs that occurred during 2019 by sites of Ukrainian NPPs is as follows: at Zaporizhzhya NPP - 6 violations; at Rivne NPP - 5 violations; at Khmelnytska NPP - 1 violation; at the South-Ukraine NPP - 1 violation [40]. There is a deviation from the normal mode of operation (abnormal event) during a failure in the operation of the NPP as stated in [43]. It may be caused by equipment failure, external influences, personnel errors or deficiencies in the procedure. 34 anomalous events were recorded in 2017, during the investigation of violations and deviations in the operation of Ukrainian NPP power units. Their distribution was: mechanical damage - 12 events; faults in the electrical part - 12 events; staff errors - 6 events; not defined - 2 events; faults in control and measuring systems - 1 event; hydraulic influences - 1 event. In the event of accidents at nuclear power plants in Ukraine number of NNEGC “Energoatom” guidelines are used to ensure safety and protection of population and territories from emergencies, to prevent their occurrence and to effectively eliminate the consequences.

Significant part (54%) of all violations in the operation of Ukrainian NPPs that occurred during 2019 led to reactor shutdown, unloading or disconnection of the unit from the network (categories P05, P08). It reduces residual design life of equipment important for safety, and reducing regulated number of load cycles of the reactor unit. Another 16% are violations (categories P03, P10) associated with the inoperability of security channels [40].

Also number and quality of cyber attacks on critical infrastructure are currently increasing. As an example Stuxnet is a computer worm that was created to attack Iran’s nuclear facilities and was discovered in June 2010 [64]. Using operating system vulnerabilities and the human factor, Stuxnet successfully hit more than 1,000 centrifuges at a uranium enrichment plant. Also in December 2014 a cyber attack was carried out on automated workplaces of nuclear power plant operators in South Korea [65]. As part of these cyberattacks thousands of phishing emails with malicious code were sent and valuable information was stolen. In autumn 2019 systems of the Kudankulam NPP station (the most powerful NPP in India) were attacked with one of the versions of the virus known as DTrack [66]. This malware was specifically compiled for distribution and operation in the

 https://doi.org/10.1051/e3sconf/202128009013

power plant network. Dtrack infected only the administrative network and did not reach the critical internal network used to control the plant's nuclear reactors. Thus threat of terrorist and cyber-terrorist acts against nuclear power plants exists and acquires new features every day.

We agree with the authors of the publication [7] who emphasize that human factor, inattention, equipment failure, natural disasters and fatal coincidence can lead to an accident at a nuclear power plant with human casualties.

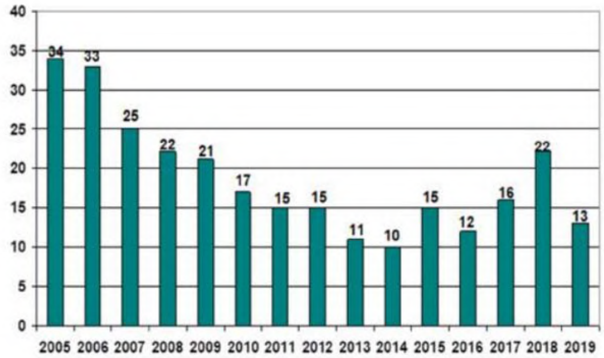

Fig. 2. Statistics on violations number in the operation of Ukrainian NPPs for 2005-2019 [40].

It should also be noted that Ukraine is still at the very beginning of creating of modern integrated system for responding to safety incidents and crises related to critical infrastructure. Thus, only in 2016 in the national legislation of Ukraine appeared definition of basic term for this area "critical infrastructure" [67].

NPP operation experience shows that accidents and incidents causes are somehow related to people (human factor) - with their attitude to safety issues. Therefore, NPP management focus is human resources, management style/methods, socio-psychological climate in production teams. NNEGC "Energoatom" is involved in process of safety culture forming in all staff beginning from the highest administrative level. There are permanent safety culture committees at the NPP. These are collegial bodies that coordinate NPP units activities in terms of maintaining and raising the level of safety culture [6].

Currently number of special measures are developed to prevent and eliminate accidents at Ukrainian NPPs, an Emergency Response System was created, special instructional materials were prepared, and so on. For example, Rivne NPP Emergency Response System is an interconnected set of human and technical resources, organizational and technical activities carried out by NPP personnel under the direction of the administration. It is done in order to prevent or mitigate impact of accidents or emergencies on personnel, the public and the environment. Main tasks of Rivne NPP emergency response system are following: ensuring readiness for localization and liquidation of accidents and other emergencies at NPPs and liquidation of their consequences; response to accidents and emergencies; implementation of measures to protect the station staff, population and environment; main tasks of the Rivne NPP emergency response system for population and environment protection; enhanced monitoring of radiation indicators of environment and irradiation of population; forecast of radiation doses of population in observation area; informing central and local executive bodies and local self-government bodies about monitoring results and forecasting of radiation doses to population; providing recommendations to central and local executive bodies and local self-government bodies on countermeasures to protect population [68].

Various measures are constantly taken to prevent emergencies at nuclear power plants. For example, mandatory psychological testing is important during employment and transfer to other positions for NPP personnel. It is stated in requirements for employeeson official websites [69]. Competition for various positions is held in following stages: 1) documents receipt; 2) psychological testing; 3) professional testing; 4) interview with commission.

The official website of Rivne NPP [70] contains a lot of information about the operation of the station and the work of staff. One of site publications states that person is a key factor in any production and its safety and enterprise production indicators directly depend on personnel working. The Rivne NPP staff development department has been operating for a year to improve the enterprise management system, improve and coordinate work with staff, assist managers in working with staff, monitor the socio-psychological climate in the power plant and improve safety culture through staff development. The personnel development department is entrusted with such important and urgent tasks as selection of personnel for certain positions, identification and development of leadership potential, organization of planning of work with personnel in departments, training of managers in management psychology and assistance in working with personnel. Specialists of the human factor management group of the personnel development department carry out number of important works with the operational personnel of the power plant on a regular basis. In addition to standard procedures, such as selection for positions at recruitment and transfer, routine surveys of working operational staff are carried out to ensure that position is suitable for professionally important qualities of the operational staff. Psychocorrectional trainings, sessions of psychoemotional unloading in a specially equipped room are carried out for employees of operational services, in case of reduction of their professionally important psychophysiological qualities. Classes are periodically held on the following topics to maintain the qualifications of operational personnel: safety culture, communication, methods of error prevention, conflict resolution, behavior in emergency situations and others. Another urgent task for the department specialists is psychological support operational personnel training on full-scale simulator [71]. Seminars for managers and their reserve on business psychology are very popular communication, leadership, teamwork and time management. For nuclear energy, openness and trust between staff and managers is important, because favorable psychological atmosphere in the team creates conditions for identifying hidden shortcomings that can be a prerequisite for serious incidents. Another important part of the specialists' activities of the personnel development department is socio-psychological climate in the NPP monitoring through anonymous questionnaires, surveys, and interviews in the units. Twice a year the specialists organize meeting of the Safety Culture Council at the Rivne NPP chaired by the General Director. Its main goal is to define strategy, plan, monitor and coordinate actions aimed at developing a safety culture. In March 2020 the survey was conducted on the Rivne NPP as whole to determine level of development of safety culture. The survey results confirmed high level of development of safety culture at the enterprise. The administration of Rivne NPP realizes that motivated, professional employees are valuable resource of organization. Staff needs constant careful work, improvement and expansion of professional knowledge and formation of safety and production culture, because safety issue at all levels of NPP activity is a priority [70].

Interview with the Rivne NPP CEO [72] highlighted main issues concern public and the power plant staff today. “Today nuclear power plant is not only the largest energy company in the region, but also local largest employer and taxpayer. Life of its entire satellite city practically depends on Rivne NPP. The main thing is that staff and equipment work reliably and safely. During pandemic we spend a lot of money to purchase personal protective equipment for staff, tests, preventive measures, including the isolation of operational staff - hotel accommodation, meals. In addition, mode of operation of our company changed significantly. It applies to certain activities such as staff training, detours, including work performed by contractors, because we have limited access to industrial site of involved employees. For some time, all this is justified and will not affect production. In the event of pandemic continuation it will certainly negatively affect work of the team” [72].

In 2020 due to pandemic COVID-19 another important factor emerged that could lead to emergencies at existing NPPs because personnel also had cases of COVID-19 and such cases continue. The NPP management takes many different measures to preserve employees health, comply with quarantine restrictions, daily check of body temperature of personnel, issue personal protective equipment, transfer to remote work of individual employees, etc. However, NPPs are enterprises where it is not possible to transfer large number of employees to remote work because many work processes have to be performed by people. Therefore, there is a risk with critical number of station employees who have to be at work every day or in shifts. Table 1 presents data on personnel number at Ukrainian NPPs for November 2020. Of course employees’ number is not accurate due to monthly changes.

Table 1. Data on personnel number at Ukrainian NPPs for November 2020.

NPP	Number
Zaporizhzhya NPP	More than 11000 workers
South-Ukraine NPP	More than 8500 workers
Rivne NPP	More than 7800 workers
Khmelnytska NPP	More than 5000 workers
Total	32300 workers
South-Ukraine NPP	More than 8500 workers

Fig. 3 shows location of nuclear power plants in Ukraine with their characteristics according to [73]. According to Fig. 2 Zaporizhzhya NPP has 6 VVER-1000 units and it is the largest in terms of staff (over 11,000 employees), South-Ukraine NPP has 3 units VVER-1000 and it is the second largest in terms of staff (over 8500 employees), Rivne NPP has 2 power units VVER-1000 and 2 power units VVER-440 and it is the third in terms of staff (over 7800 employees) and Khmelnytska NPP has 3 power units VVER-1000 and is the smallest (over 5000 employees) in terms of staff among operating stations.

Fig. 4 contains data [74] on the spread of COVID-19 coronavirus infection in Ukraine by region for of December 23, 2020. It shows number of already confirmed cases and the total number of COVID-19 patients in each region since the epidemic beginning. Also, the total number of people infected with COVID-19 is 989,642, among them 615,660 are recovered, and there are 17,172 deaths. If we compare Figures 4 and 5 we can assume that at the moment the staff of Rivne NPP and Khmelnitsky NPP is in high danger zone. They therefore need special safety measures, social and psychological support because they are located in the areas with large number of cases of COVID-19. It can not be NPP employees, but for example their relatives, close friends, neighbours and others. Therefore, it is necessary to pay attention not only to physical condition of employees, but also to the psychological health of staff.

3.3 Measures and recommendations for social and psychological support of NPP personnel

The world community faced uncertainty period due to COVID-19 pandemic. In many countries, the pandemic threatens not only human life but also economic, social and other spheres of public life [5]. Social consequences of the pandemic are: breaking family ties, disrupting social networks, destroying community structure and resources, declining trust, increasing gender-based violence, and more. Psychological consequences of emergencies are their impact on different levels of mental functioning - emotional state, behaviour, relationships. They can be related to: problems that existed before (mental disorders, alcohol or other chemical abuse); problems that arisen a result of emergency (non-pathological distress, mental disorders: depression, post-traumatic stress disorder (PTSD), anxiety disorders, adaptation disorders) [4]. Mankind found itself in situation of change and uncertainty for which it was not ready. The pandemic provokes increased anxiety, distress and other reactive states in people. Also, one of the specific features that causes socio-psychological problems is quarantine restrictions and inability to contact directly in usual circle of social interaction [5]. Each person’s response to emergencies is different because each person has different resources and opportunities to recover [4]. Therefore, wide range of citizens began to need psychoprophylaxis, crisis counseling and socio-psychological support.

Currently, the pandemic regime was introduced in the world. This period is characterized by alarming information content, increased psychological pressure due to unfavorable epidemiological situation. Symptoms of frustration, hopelessness, fear, anticipation of threat, loneliness, social isolation and alienation, sleep disturbances and nightmares, irritability and outbursts of anger are just a few of PTSD symptoms seen in people in different countries. Such manifestations are observed in the population of Ukraine. The work [5] identified socio-psychological consequences of the pandemic for individual:

• loss of basic sense of safety;

• increase in anxiety and fear (for example, get sick, lose your ability to work);

• new living and working conditions (remote work in online format);

• mixing social roles (for example, home office, when you need to combine several roles of wife-mother-specialist/husband-father-worker, etc.).

Fig. 3. NPP placement in Ukraine [73].

Fig. 4. Statistical data on COVID-19 spread in Ukraine by the regions [74].

In 2007 the United Nations together with the governments of various countries adopted the "Guide to Mental Health and Psychosocial Support in Emergencies". The document states that the main goal is to provide humanitarian actors and communities with strategy to plan, implement and coordinate system of minimum multisectoral response to protect and improve mental health and psychosocial well-being of population in emergency midst [4].

The article 38 "Psychological protection of the population" states [56]: 1) measures of psychological protection of population are aimed to reduce and neutralize negative mental states and reactions among population in case of threats and emergencies and include: planning activities related to psychological protection; timely application of licensed and permitted in Ukraine informational, psychoprophylactic and psychocorrectional methods of influencing individual; identification with help of psychological methods of factors that contribute to emergence of socio-psychological tension; use of modern psychological technologies to neutralize negative impact of emergency factors on population; implementation of other measures of psychological protection depending on current situation; 2) organization and implementation of psychological protection measures of population are entrusted to central body of executive power which ensures formation and implementation of state policy in the field of civil protection.

The publication [5] identifies current research problems in the field of health psychology of personnel of organizations and enterprises in the pandemic COVID-19:

1) *in organizational psychology*: essence of psychological health and well-being of staff in the organization in "normal" conditions and in the pandemic COVID-19; psychological features of personnel activity in self-isolation conditions; ensuring Work Life Balance in crisis situations; psychology of change management in organization in the context of the COVID-19 pandemic (adaptation to change, introduction of new forms of work, teamwork, etc.); new forms of personnel communication in organizations during the COVID-19 pandemic, new manifestations of conflicts in the organization during the COVID-19 pandemic; prevention of occupational stress and burnout in representatives of risky occupations (military, doctors, firefighters, etc.) and in other occupational groups of personnel during the COVID-19 pandemic; psychology of gradual exit of organizations from quarantine etc.

2) *in the field of psychological assistance and psychological training of personnel in the organization*: distance learning of personnel during the pandemic COVID-19: opportunities and limitations; psychological features of digital technology use, etc.

Also, psychologists-practitioners in [5] noted trends in client requests to psychologists and psychotherapists during COVID-19: a) existential issues: isolation, meaninglessness of life and what is happening (deprivation of meaning), suicidal thoughts, etc.; b) psycho-emotional states: fears (especially fear of death), anxiety, neurosis, stress, panic attacks, exacerbation of phobias, depression, impulsive-compulsive disorders; increased emotionality, exacerbation of neurotic states, etc.

Consider social system "NPP Staff" it should be noted that for NPPs of Ukraine such group can be on average 5000-10000 people - from worker to control panel operator or management of NPP. Subsystems are easily identified in this system: operational personnel, repair and maintenance personnel, seconded personnel, managers. Also, each subsystem is divided into shops, sections, changes according to NPP structure. Each of subsystems consists of tens or hundreds of elements (individuals) that form certain group (team) united by common goals and objectives. Each group performs specific (regulated) task, has its own hierarchy and living space. Of course, each individual has its own specific responsibilities but all are interdependent [62].

Decision on candidate's professional suitability for work at NPP is made by the commission on professional selection taking into account recommendations of the personnel department, incoming knowledge control, results of the interview with the structural unit head to which the candidate comes and conclusion of psychophysiological examination [6].

During the pandemic NPP personnel received an additional stress as work on critical infrastructure is considered to be quite complex and responsible.

Considering impact of negative stress on employees activities it is necessary to study conditions that contribute to optimization of their activities in extreme situations. An important factor in increasing psychological readiness ispresence of action plans in different types of extreme situations, their internal modeling and their activities in them. This not only increases psychological readiness but also helps to master new algorithms [47].

At present it is important for organizational psychologists and special departments to work with NPP personnel to diagnose mental health problems in organization during the COVID-19 pandemic and to provide appropriate psychological assistance to personnel. Such socio-psychological support can be implemented through webinars, psychological training, online and "regular" psychological counseling, etc.

Taking into account the above recommendations will create controlled situation of verbal support and jointly develop rational behavior and strategy to overcome situation and solve pressing psychological problems. Of course, all these global crisis processes require new approaches not only in individual psychological counseling but also in group of work and in creating psychological support for organizations staff. After all employees who are in state of anxiety lose concentration, perform tasks longer, make difficult decisions, become more conflicted, and so on [5].

Analysis of the NPP official websites showed that various measures for psychological support were developed for station staff: 1) people who undergo psychological testing are accepted to work at station as NPP is a potentially dangerous object; 2) various trainings are conducted (development of leadership qualities, conflict prevention, development of stress resilience, teamwork, etc.); 3) special rooms of rest and relaxation are created.

https://doi.org/10.1051/e3sconf/202128009013

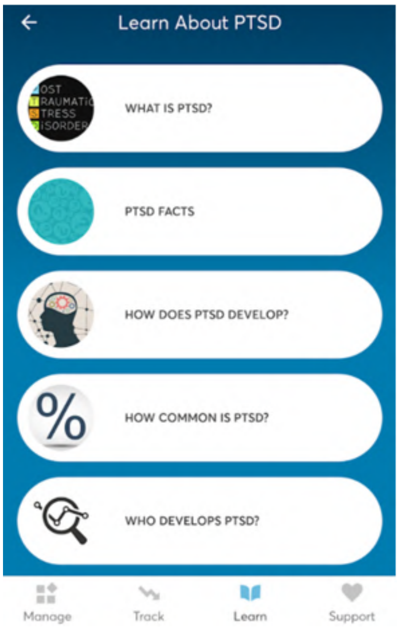
Psychologists working at NPPs can use special questionnaire to establish referral criteria in event of serious mental problems occurring in staff. In [4] it was emphasized that stress can cause various reactions, including psychological (can be manifested in certain emotions, thoughts, behavior), physical (certain bodily manifestations) and others. Need for referral to receive the necessary services becomes clear depending on severity of these symptoms, their duration and the impact on daily functioning.

As a result of analysis of the scientific literature [4,5, 46-52] it was determined that there are certain types of mobile applications for mental health. People can use them on their own without psychologists help. They contain various methods and recommendations of psychologists, social workers for psychological support of the affected population.

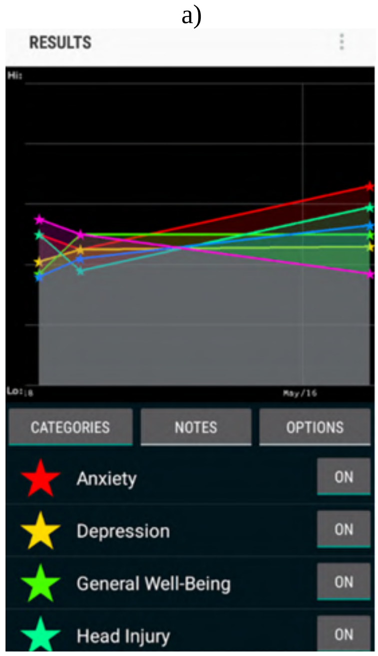
Early provision of information and training to cope with stress can prevent dangerous consequences of psychotrauma. Educational orientation of mobile applications can be key in providing psychological assistance. Because it is very important to get clear and orderly information about their condition and understand what to do next for victim of stressful events. Studying typical consequences of psychotrauma helps to better understand one's own reactions to stress, and knowledge of one's resources (constructive coping strategies) provides sense of control over these reactions. It is important to explain necessary information about mental health, psychological problems and their consequences to people. It contains the following elements: information transfer, emotional relaxation, explanation and application, self-help training [51].

Varieties of electronic services that can be used to process traumatic experiences are quite wide: informing, diagnosing, monitoring, support, reminders, communication. Mobile applications with such functions can be used at any stage of socio-psychological work in the pandemic and psychotrauma. Specialized applications contain necessary information suitable for processing various experiences (increased anxiety, avoidance of social contacts, conversations about traumatic experiences, symptoms of intrusions or hyperexcitability, etc.). Obtaining specific information can prevent prevalence of post-stress disorders and contribute to spread of good practices for maintaining mental health [51].

Mental health mobile applications are applications to support mental health. Most of them are aimed primarily at promoting of healthy lifestyle, self-assessment, self-monitoring, prevention, as well as step-by-step treatment of various disorders. Such functions can be used by person both independently and as material to provide psychologist or psychotherapist. Effectiveness of such electronic interventions in depression, psychosis, increased anxiety was proven. Apps for tracking mood swings, coping with stress, sleep disorders and eating habits are effective and popular. For example, the *PTSD Coach* supplement is used to prevent and overcome the symptoms of PTSD as an extreme manifestation of psychotrauma. *Bust PTSD, Breathe2Relax, Beat PTSD, Tactical Breather* applications are aimed to improve self-healing skills through meditation and concentration on breathing. You can effectively monitor mood changes with the *T2 Mood Tracker* monitoring application. *Provider Resilience, LifeArmor, AZNG Be Resilient Program, Develop Your Resilience* applications offer useful psychological skills. And the *PFA Mobile* and *Care4Caregiver* applications are designed specifically for professionals as guides to working with victims [50]. Examples of mobile applications are presented in Fig. 5.



a)



b)

Fig. 5. Examples of mobile applications work: PTSD Coach (a) and T2 Mood Tracker (b).

The service "Mobile psychological assistance" is presented on the site [54]. The program allows user to assess its own condition in such categories as sleep quality, depression and PTSD, as well as contains text materials sorted in menu and notes on symptoms of PTSD; anger management; depression control; alcohol and drug addiction; stress; relations with relatives; psychological resilience. There are also tools to assess your own condition; videos about PTSD; as well as list of psychological care services. The application "PFA Mobile Ukraine" contains recommendations for providing first psychological assistance to both victim himself after receiving a trauma and those who find themselves next to such a person - colleagues and relatives. However, it is important to remember that use of psychological mobile application cannot replace deep-seated methods of psychotherapy. So it should be considered as primary psychological assistance of individual. Advantages of using specialized applications are following [50]:

• it saves time that would be spent for specific information or specialist searching;

• it overcomes barrier of space and resource base;

• it can be used on different devices by linking to virtual account;

• it is free (in the vast majority) or has much lower cost than individual meetings with specialist;

• it to the user, providing his autonomy;

• it is suitable for those who are wary of contact or have prejudices against psychologists;

• it corresponds to specific psychological problem and is aimed at its solution;

• it allows you to track changes in the state, which encourages the user to continue working, cultivates in him a commitment to self-help and help.

4 Conclusions

In 2020 COVID-19 led to the pandemic and caused an emergency worldwide, threatening lives and population health with large number of deaths and injuries. Also, during the pandemic there was (and continues to be) a violation of normal living conditions, significant material damage to economies of different countries. Quarantine restrictions affected social, educational, cultural and spiritual spheres of society. There is urgent threat to operation of critical infrastructure because the pandemic led to large numbers of hospitalized people or being isolated and treated at home. Operation of critical infrastructure facilities is strategic importance for proper functioning of any country. It includes energy, chemical, transport and other enterprises, and in particular nuclear power plants.

Scientists determined that threat of potentially dangerous situations remains and can cause radioactive and chemical contamination of the environment and harm the health of personnel and the public despite introduction of technologies and automated monitoring systems at nuclear power plants. Also one of the key means to ensure NPP safety operation and its further improvement is to take into account previous experience of operation and elimination of initial stage of emergencies. It includes accounting and analysis of disturbances in operation of stations, implementation of corrective measures to prevent violations. Analysis of violations statistics in operation of Ukrainian NPPs over the past few years shows that violations above the 1st class (anomaly) on the international INES scale have not occured at these power units. Indeed, in energy sector of Ukraine in recent years no threats were identified associated with emergencies risk due to equipment failures or extreme natural phenomena. However, there are additional risks associated with growing threats of nuclear terrorism, armed conflict in southeastern Ukraine and problems related to the COVID-19 pandemic (diseases of NPP personnel or their relatives). Therefore, problem of psychological health of NPP personnel during the pandemic is one of the relevant topics for research.

Currently, number of special measures were developed to prevent and eliminate accidents at Ukrainian NPPs, special instructional materials were prepared and the Emergency Response System was created. It is interconnected set of human and technical resources, organizational and technical measures or mitigating impact of accident or emergency on personnel, public and environment.

Also, psychological testing is mandatory for plant personnel during employment and transfer to other positions in order to prevent emergencies at NPPs. Various trainings (development of managerial qualities, conflict prevention, emotional burnout, etc.) are conducted and rooms for relaxation and rest are created.

Currently, extreme situations of activity are analyzed in three main aspects in psychological research: as features of situation itself, as a set of conditions of activity; as features of subject of activity in extreme situations, its readiness; as features of consequences of activity in difficult conditions of professional activity. Therefore, work of NPP personnel can be considered as a "set of operating conditions", i.e. work on potentially dangerous object. Ukraine is also implementing an international "Guide to Mental Health and Psychosocial Support in Emergencies". The terms "mental health" and "psychosocial support" mean measures aimed at protecting and promoting psychosocial well-being, as well as prevention and/or treatment of mental disorders.

Socio-psychological support is important to promote mental health during the COVID-19 pandemic especially for critical infrastructure workers. Stress associated with uncertainty and threat to health can have negative consequences for well-being and mental health of employees and can result in depression, emotional exhaustion, and anxiety.

Timely detection and appropriate work to restore mental health during the pandemic is an equally important area of work along with providing medical care to the population. Psychological mobile applications should be considered as economical way of primary care - proper psychological information of the population [51].

NPP is a potentially dangerous object, so, recommendations were prepared for social and psychological support of NPP personnel:

1) organize a system of informing staff about measures to prevent and reduce the risk of COVID infection; it in turn will help restore sense of safety and reduce anxiety level of employees;

2) conduct trainings or webinars on organizational issues online; it will discuss rules, advantages and difficulties faced by employees during the quarantine

period, ways to overcome these difficulties, introduction of mentoring system;

3) organize team building, meetings, rituals online (for example, morning online meetings over cup of coffee to stabilize psycho-emotional state of employees);

4) carry out personnel screening procedure; if disorders of adaptation take place against background of more pronounced psychological trauma and depression it is necessary to refer to psychotherapist or psychiatrist;

5) carry out once every few months testing and interviewing staff;

6) create positive image and commitment to psychological counseling and seeking psychological help;

7) advise NPP employees to independently use specialized mobile applications for psychological support.

Abstract. There has been established in the article the correlation and regression relationship between the factors of the country's development and the level of environmental safety on the basis of identifying the patterns of certain factors sets influencing the volume of harmful emissions into the atmosphere. On the basis of modeling, there has been carried out the analysis of individual groups of factors influencing the volumes of harmful emissions in the countries selected for the study. The nature and degree of influence of the selected factors on the resulting indicators (volumes of harmful emissions) have been determined. It has been found that the number of these factors is significantly higher in France than in Ukraine. This is due to both the political and economic situation in the country. The level of energy efficient technologies implementation and environmental restructuring of business entities are no less significant. The ranking of factors has been carried out based on the value of the correlation coefficient within a separate group and each country. There are also highlighted differences in the research results and their reasons.

1 Introduction

In today's world, among the dominant problems, there are environmental ones associated with climate change as they threaten the further development of mankind. The countries participating in the United Nations Framework Convention on Climate Change (1992) have assumed international obligations defined in the Kyoto Protocol (1997) and the Paris Agreement (2015) regarding the reduction of greenhouse gas emissions. This necessitates states with different levels of development to form and implement an effective environmental policy, which will reduce anthropogenic influence and stimulate the development of a "green" economy.

Researchers often focus on identifying and establishing the nature and types of relationships between various phenomena and processes occurring in society (for example, the level of economic development, urbanization, the increase in the use of alternative and traditional types of energy, research, investment and innovation activities) and their influence on environment. For example, to analyze the relationship between emissions, natural resources, revenues and renewable energy in the BRICS countries, there has been applied the AMG method [1]. Natural resources were used as a control variable that showed the relationship between revenues and emissions in the EU-5 countries [2]. The relationship between income, energy consumption and carbon emissions in the United States was studied by [3].

The studies of countries with different income levels were conducted by [4]. The results have shown that energy consumption per capita is the main cause of carbon dioxide emissions. Studies [5, 6] have shown that green innovation is the main factor affecting carbon emissions.

There are proposed a modern information and analytical system for monitoring atmospheric air pollution and considered the features of the air quality index in [7, 8, 9, 10]. A schematic diagram of the structural organization and relationships between the subjects of environmental monitoring has been developed in [11]. New forms of data presentation on monitoring technogenic loads and risks, reflecting the dynamics of ecological situation in the space of informational features, were proposed in [12].

A prototype of a monitoring system is presented to solve monitoring problems [13, 14]. There are combined methods that enable us to predict the influence of technogenic activities on human health and are an effective complex of environmental monitoring studies in [15]. There are presented the developed mathematical models that allow predicting atmospheric pollution and are an effective tool for supporting decision-making on the problems of environmental safety of the atmosphere in [16].

* Corresponding author: pobigunserg@gmail.com

The risks to public health associated with air pollution have been analyzed and evaluated in [8, 17, 18]. Mathematical models have been developed to reduce the spread of pollutants in the atmosphere [19, 20].

A significant influence on air pollution is carried out by the quality of the fuel; the study of the fuel quality management system, the environmental and economic analysis of the developed system is made in [21, 22]. New mathematical tools have been developed in [23, 24, 25] to determine the distribution in space and time of the technogenic load on the atmospheric air from gas wells. The issues of modeling the dispersion of the atmosphere taking into account the mathematical modeling of the emissions formation are shown in [26] and ways of automating the process of scenarios development modeling are highlighted in [27].

The results of scientific research on the reduction of pollution by the oil and gas complex that allow avoiding the ingress of harmful substances into the environment are presented in [28]. The species composition and life status of biocenoses located on the territory of the wells are investigated in [29]. The extent of the environment destruction and the decline in biodiversity are investigated in [30].

An approach and recommendations for increasing the level of environmental safety in areas of oil and gas fields' development are offered in [31, 32]. Offers and their implementation to reduce the influence from the activities of oil and gas facilities in the process of wells drilling are presented in the following scientific papers [33, 34, 35, 36, 37, 38].

The influence of renewable energy on sustainable development was studied in [39, 40]. The main directions of ecological modernization with the use of economic levers to reduce the negative influence on the environment are considered in [41]. The study of functional dependences of factors influencing the amount of waste using the praximetric method, variance and regression analysis was carried out in [42, 43]. The influence of social and scientific-intellectual factors, namely the relationship between the education quality of employees and results of their work are studied in [44, 45].

2 Objective and tasks of research

The aim of the study is to analyze the patterns of social, environmental, economic, scientific and intellectual factors influence on the volume of harmful emissions, such as carbon dioxide, sulfur dioxide and nitrogen oxide, in order to determine possible ways of affecting the level of environmental safety.

To achieve the goal, the following tasks were set:

- to carry out a correlation analysis for assessing the proximity of the relationship and the nature of the factors affecting the level of harmful emissions;

- to analyze the influence of certain factors groups on harmful emissions for countries with developed economies and developing countries;

- to identify priority causes that lead to changes in factors affecting emissions.

3 Materials and methods

Statistical data of Enerdata, World Bank, World Statistics, Eurostat, Index Mundi, OECD, Statista, International Energy Agency for 1999-2018 were used as materials for the study, namely the level of harmful emissions in the atmosphere: CO_2, SO_2, NO_x and such parameters - factors as: energy intensity of GDP, investment level, rent payments, population density, energy consumption, etc. The object of the research is France as a country with a high level of economic development and Ukraine as a country with a low level of economic development.

Correlation analysis was applied to determine the nature and degree of social, economic, scientific and intellectual factors influence on the amount of harmful emissions, such as carbon dioxide, sulfur dioxide and nitrogen oxides. The study has been based on the coefficients of correlation and determination (approximation), linear and nonlinear (quadratic, logarithmic, inverse, power) functions. The value of the correlation coefficient sign allows us to assess the direction of the selected factors influence on the resulting indicators (the number of emissions). The type of function enables us to understand the nature of the influence: if it is a simple linear one, then the increase or decrease in the indicator occurs evenly. If it is a non-linear one, then we get different levels of acceleration or deceleration of the indicator change depending on the factor change.

4 Results and discussion

A change to the climate policy was the adoption of the Kyoto Protocol, which has been in effect since 2005. Despite all the positives of the Kyoto Protocol, it had several drawbacks. One of the main drawbacks was that not all states adhered to it in good faith, in particular the United States never ratified the Protocol despite the fact that all states proclaimed the importance of combating climate change. Therefore, the Paris Agreement came to replace the Kyoto Protocol in 2015. Both documents are based on the principles of the "green economy" and aim to prevent climate change, but contain a number of differences, the main of which are:

- in the Paris Agreement, any sanctions for greenhouse emissions were canceled and each country determined for itself the amount of emission reductions. Thanks to this approach, more than 160 countries have joined the new agreement, some of which have not previously assumed commitments to reduce emissions;

- the Kyoto Protocol allows cross-border trading in quotas. This practice gave rise to opacity in the national accounting of greenhouse emissions and made it possible to implement corruption schemes, incl. in Ukraine.

- the Paris Agreement does not provide for interstate trading in quotas. Countries will be able to use market mechanisms to achieve their emission reduction targets, buying international carbon credits, which should reflect real emission reductions, and detailed rules for the operation of new market mechanisms should be approved at the next Conferences of the Parties to the UN Framework Convention on Climate Change.

- the Paris Agreement provides for the technological and financial assistance by developed countries in emissions reduction to developing countries.

One of the most difficult issues of this agreement is the adoption of a new differentiation of countries into developed and developing countries in order to resolve the issue of who will provide financial and other assistance, and who will receive it. Traditional donors - the EU, USA, Canada and other developed countries do not give up their commitment and continue to be the leaders, providing and increasing funding to combat climate change. At the same time, among the countries that do not fall under the definition of "developed" - Saudi Arabia, South Korea, Singapore, there are those that are able to provide assistance, but do not want to do so. However, the Agreement states that they can provide assistance voluntarily [46].

Since the object of the study is Ukraine and France, based on the above, we note that France, as a result of the adoption of the Paris Agreement, is a country that provides financial assistance and Ukraine, in its turn, is a developing country and is applying for donor funds to fulfill the terms of this agreement.

For a deeper analysis of the level of such emissions as carbon dioxide, sulfur dioxide and nitric oxide into the environment, we select social, environmental and economic indicators from the groups of factors, which, in our opinion, have great influence on the level of harmful emissions and determine the main reasons for this influence, and opportunities to change them using the tools of the "green economy".

The criterion for assessing the closeness of the relationship between the studied pairs of emission indicators and the corresponding factors is the correlation coefficient. The influence assessment is carried out, assuming the possibility of the existence of not only a linear relationship, but also the possibility of various forms of nonlinear influence existence. For the study, there were chosen the following forms of non-linear connection: power, exponential, quadratic, inverse and logarithmic. Based on the analysis of the correlation coefficient value, there is selected the corresponding form of relationship, for which the value of the correlation coefficient is the largest (Tables 1-8).

Table 1. The results of analyzing the influence of the social factors set on harmful emissions in Ukraine.

Name of the factor, designation	Form of the detected relationship	The nature of the identified relationship
Human Development Index, X1	For SO_2 and NOx - not detected for CO_2 – a square relationship	The factor increases, the indicators decrease
Population density, X7	For SO_2 and NOx - not detected for CO_2 – an inverse relationship	The factor increases, the indicators increase

In our opinion, it is interesting to compare individual factors for the two countries, which have a different effect on the resulting indicator, in particular, the rent for the use of natural resources $ in Ukraine increases, and at the same time, the level of SO_2 and NOx emissions show an upward trend, and in France, in its turn, this factor also increases and the level of emissions decrease.

Table 2. The results of analyzing the influence of the social factors set on harmful emissions in France.

Name of the factor, designation	Form of the detected relationship	The nature of the identified relationship
Human development Index, X1	Quadratic	The factor increases, the indicators decrease
Population density, X7	Inverse	The factor increases, the indicators decrease

Table 3. The results of analyzing the influence of the environmental factors set on harmful emissions in Ukraine.

Name of the factor, designation	Form of the detected relationship	The nature of the identified relationship
	Ukraine	Ukraine
Energy intensity of GDP at constant purchasing power parities (koe/$ 2015), X2	For SO_2 and NO_x - not detected for CO_2 – 1/X) (a direct relationship)	The factor increases, the indicators increase
Domestic consumption of coal and lignite (Mt), X8	Power	The factor increases, the indicators increase

Table 4. The results of analyzing the influence of the environmental factors set on harmful emissions in France.

Name of the factor, designation	Form of the detected relationship	The nature of the identified relationship
	France	France
Energy intensity of GDP at constant purchasing power parities (koe/$ 2015), X2	Quadratic	The factor increases, the indicators decrease
Share of renewable energy sources in electricity production (%), X3	Power	The factor increases, the indicators decrease
Domestic consumption of coal and lignite (Mt), X8	Power	The factor increases, the indicators increase

This is due to the fact that the rent for the use of natural resources in Ukraine is not large and it does not induce to reduce emissions, and in France it is an effective tool as high rent encourages enterprises to reduce emissions in accordance with EU legislation.

The production factor (value added) in Ukraine and France tends to increase, which is a positive phenomenon, however, in France, emissions show a decrease, while in Ukraine they are growing. The reason for this situation may be the use of extensive factors of production, which give an increase in production volumes, raw materials prevail, services, tourist services, the use of intensive factors of production, and the latest technologies prevail.

Table 5. The results of analyzing the influence of the economic factors set on harmful emissions in Ukraine.

Name of the factor, designation	Form of the detected relationship	The nature of the identified relationship
Rent for the use of natural resources, $, X4	A linear relationship (for CO_2 – not detected)	The factor increases, the indicators increase
Production, value added (current USD), X5	Quadratic (for CO_2 – not detected)	The factor increases, the indicators increase
Foreign direct investment, net inflows (BoP, current USD), X6	A linear relationship (for CO_2 – a low level of relationship)	The factor increases, the indicators increase
Grain harvest (kg per hectare), thousand, X9	For SO_2 i NOx – not detected, (for CO_2 – a quadratic one)	The factor increases, the indicators decrease
Total energy consumption, X10	Power	The factor increases, the indicators increase
Transport services (% of commercial services import), X12	For NOx – a power relationship, for SO_2 – a logarithmic one, for CO_2 – a quadratic one	The factor increases, the indicators increase
Unemployment, total (% of total labor force) (ILO modeled estimate), X13	Inverse (for CO_2 – not detected)	The factor increases, the indicators decrease
Exports of ores and metals (% of merchandise exports), X14	Logarithmic (a low level of relationship)	The factor increases, the indicators decrease

With an increase in research and development costs, emissions in Ukraine increase, while in France they decrease. This gives grounds to assert that money is spent on the wrong developments in Ukraine, and in France, intellectual developments are sufficiently introduced at enterprises that ensure emissions reductions.

In accordance with the obtained calculations, we will rank the factors within each group according to the values of the correlation coefficient (Tables 9-10): 1 - the highest level of influence, 3 - the lowest level of influence (for social, environmental, scientific and intellectual factors), 1 - the highest level of influence, 8 - the lowest level of influence (for economic factors).

Summing up, we can say that for all groups of factors for both countries, it is worth highlighting a number of effective tools that make it possible to reduce emissions by decreasing the negative influence of individual factors, as evidenced to a greater extent by statistics on the main indicators of France. In its turn, Ukraine has the opportunity to study the experience of France and other countries, in order to implement effective socio-economic and environmental policies, measures in the context of reducing emissions in various fields of activity, thereby observing the foundations of a green economy.

Table 6. The results of analyzing the influence of the economic factors set on harmful emissions in France.

Name of the factor, designation	Form of the detected relationship	The nature of the identified relationship
Rent for the use of natural resources, $, X4	Quadratic	The factor increases, the indicators decrease
Production, value added (current USD), X5	Inverse (for CO_2 – a low level of relationship)	The factor increases, the indicators decrease
Foreign direct investment, net inflows (BoP, current USD), X6	Power (low level of relationship)	The factor increases, the indicators increase
Grain harvest (kg per hectare), thousand, X9	Not detected	
Total energy consumption, X10	Power	The factor increases, the indicators increase
Transport services (% of commercial services exports), X11	Power	The factor increases, the indicators increase
Transport services (% of commercial services import), X12	Quadratic	The factor increases, the indicators increase
Unemployment, total (% of total labor force) (ILO modeled estimate), X13	Exponential (a low level of relationship)	The factor increases, the indicators increase
Exports of ores and metals (% of merchandise exports), X14	Inverse (a low level of relationship)	The factor increases, the indicators decrease

Table 7. The results of analyzing the influence of the scientific and intellectual factors set on harmful emissions in Ukraine.

Name of the factor, designation	Form of the detected relationship	The nature of the identified relationship
Property Fees, Payments (BoP, Current US Dollars) Research and development costs $, X15	Quadratic (for CO_2 – not detected)	The factor increases, the indicators increase
Research and development costs, $, X16	A linear relationship (for CO_2 – not detected)	The factor increases, the indicators increase
Patent applications, residents, X17	Logarithmic for CO_2 (a low level of relationship)	The factor increases, the indicators increase

Summarizing the reasons that lead to changes in the factors affecting the volumes of emissions, it should be noted that they take place at all levels, namely at the levels of cooperation between different countries, unions (global), state, local and individual. In particular:

1. Key global initiatives that demonstrate attempts to find a global consensus around the increasing importance of the environmental factor in the activities of international organizations, institutional investors and TNCs, as well as in the politics of the countries of the world, reflected in the foundations of the transition to a "green" economy.

Table 8. The results of analyzing the influence of the scientific and intellectual factors set on harmful emissions in France.

Name of the factor, designation	Form of the detected relationship	The nature of the identified relationship
Property Fees, Payments (BoP, Current US Dollars), Research and development costs $, X15	For NOx and SO_2 – a logarithmic relationship. For CO_2 - a linear relationship.	The factor increases, the indicators decrease
Research and development costs, $, X16	A linear relationship	The factor increases, the indicators decrease
Patent applications, residents, X17	Inverse (for CO_2 – 0,46 a low level of relationship)	The factor increases, the indicators decrease

These initiatives are, first of all, declared in the documents as the goals that must be achieved by a specific time (the 2030 Agenda for Sustainable Development, the Sustainable Development Goals and the Paris Agreement), at the level of the European Union, the European climate law. Responsibilities for the implementation of the measures in these documents are assigned directly to the governments of each country that ratified these regulations. Therefore, both in Ukraine and in France, the following documents were adopted on their basis at the state level. The political and legislative framework for the climate policy in Ukraine is provided by the Law "On the Basics of Monitoring, Reporting and Verification of Greenhouse Gas Emissions", Ukraine 2050 Low Emission Development Strategy (LEDS), the CONCEPT of State Climate Change Policy Implementation until 2030. In France, the main regulatory documents on the implementation of international agreements are the Law on Energy Transition for Green Growth (LTECV), the National Adaptation Plan for Climate Change, and the National Low Carbon Strategy. That is, the legislative base has been formed, but there are a number of shortcomings. In particular, it is necessary for Ukraine to create an integral and effective regulatory framework for a system of regulating harmful emissions, fully adapted to global international agreements. The priority here should be a set of legislative actions that are relevant to improve taxation of emissions, as well as the use of funds received from tax revenues for emissions. After reviewing the French regulations, a minor flaw can be considered the difficulty of understanding them, as they cover different areas together with very detailed provisions for implementation at different levels and with different time frames.

2. The next tool that can ensure the reduction of emissions and funding budgets for improvement of environmental situation and promotion of green business development is the application of effective state fiscal policy. Today in Ukraine, rates for harmful emissions remain one of the lowest in Europe (as an example, 0.33% per ton of CO_2 emissions in 2019), while in France they are one of the highest and grow from year to year (€35 per ton of CO_2 emissions in 2019). In addition, the list of environmental taxes has 20 items in France, and according to Eurostat, they are classified into the following categories: energy, transport, pollution, subsoil. In Ukraine, however, there is no clear classification of the

environmental tax to the object of taxation. Also, revenues from the environmental tax are spent opaquely and ineffectively. Companies that pollute the environment have been paying fees since 2011, but most of environmental problems still remain unsolved. In addition, low rates of environmental taxes do not stimulate business entities to invest in environmental protection measures. In France, however, high environmental tax rates are often the cause of strikes in the country. One of the reasons is high fuel rates. However, not all funds are used for environmental activities, and most of them are directed to pay for the budget deficit (from 34 billion euros that the French government received from a fuel tax in 2018, 7.2 billion euros were allocated for environmental activities).

3. Studies show that environmental taxation of European countries has proven its effectiveness in the implementation of environmental policy. This contributed to the rapid production of innovative technologies in environmental protection measures and the reduction of harmful emissions [46].

4. Renewable energy sources help solve sustainable development challenges by reducing air, water and soil pollution [47]. It is the increase in the use of renewable energy that is one of the priority directions for the implementation of the countries state policy in the field of energy efficiency. In France, utilities use the Energy Efficiency Certification Scheme (also known as "white certificates") to meet their energy reduction targets, which in turn include performing energy audits, government granting targeted subsidies for energy efficient equipment, using renewable energy sources and the like. The white certificate scheme started in France back in 2006. Improving energy savings in the residential sector, which is one of the largest consumers of energy resources, is also the main task of the climate and energy policy of each country. In France, an important part of the country's Policy Strategy for Decarbonizing the Buildings Sector is a tax credit scheme for costs associated with energy efficient renovation works, the so-called The Energy Transition Tax Credit (CITE). In Ukraine, the instruments of state support for the population in the sphere of energy efficiency are two nationwide programs to improve the energy efficiency of the housing stock: the so-called "Warm credits", handled by the State Agency on Energy Efficiency and Energy Saving of Ukraine "SAEE", and the Energy Efficiency Fund program "Energodim".

5. One of the most important roles in the development of innovative processes in the energy sector is played by the governments of countries, which often fund high-risk research, as well as new low-carbon technologies, which, as a rule, are not cheap and are characterized by a plurality of market prices. One of the most effective ways to assess the implementation of clean energy technologies is to assess the level of public investment in energy R&D and demonstration activities (R&D and DA) and identify the relationship between these investments and technology development. The total amount of state funding for energy R&D and DA in 2018 in France is 1.526 million euros, which puts it in first place among the EU countries, in Ukraine this information is absent. The assets received are often intangible, the returns are uncertain, and the investment in innovation is not always easy and quick to return. This is where government support is an important resource for long-term finance. Policy instruments can be used to ensure access to financing risky projects. As a result, many high-risk private sector innovations are based on early stages of publicly funded research and programs.

5. Conclusions

Based on the analysis, there have been identified effective legislative, organizational and management tools that will contribute to reducing emissions for developing countries:

- formation, bringing up to European standards of the legal framework on regulation, management and control in the field of the environment;
- maintaining an effective fiscal policy in matters of rent payments, environmental taxes and fines;
- intensive use of "green investment" instruments, namely "green" bonds;
- reduction in energy consumption due to the use of certification schemes for the result of energy conservation, the so-called "white certificates";
- an increase in the amount of public investment in energy R&D and demonstration activities;

The research results allow in the future building multivariate econometric models to assess the complex influence of such factors on emissions and formulating recommendations for improving social, environmental and economic policies to ensure the reduction of harmful emissions.

Abstract. Modern tourism is a sector of the economy that is developing very fast, for the last 10 years the growth was 25%. According to UNEP and the WTO, tourism is seen as a growing sector in contrast to the manufacturing sector. According to experts, the growth rate of the tourism industry will remain high, although global and regional structures of tourism change over the years (in recent years due to terrorism, the development of various diseases, natural disasters, pandemics, etc.). In 2019, about 1,500 million international trips were made. The same data indicate that the growth of tourism is due to developing countries. In countries with weak regulation of the market economy, tourism development can become a real threat to the quality of the environment. Therefore, the further development of tourism, in general, is possible only through its greening and finding a balance between economic and social development, taking into account environmental factors.

1 Introduction

Current scientific publications in this field relate mainly to the formation of concepts, conceptual framework and general principles of sustainable tourism development. Tourism can be defined as a system of balanced tourism, which deals with the growth of the developing market due to the growing interest in the natural environment. With the growth of tourist services, the expansion of tourist infrastructure, the ecological situation in the territories in connection with their recreational use can reach a threatening state. However, the literature on balance often contains broad definitions based on an immeasurable ideal state, which can be governed by a number of basic principles, which are often vague and contradictory.

The issue of sustainable tourism development is relevant on the agenda of world meetings on environmental protection and tourism development in recent years.. In Ukraine was developed "Strategy for sustainable development of tourism and resorts" [1, 2]. Scientific publications of recent years are devoted to substantiation of scientific bases of balanced development of tourism, separate aspects of maintenance of balanced development of tourist regions [3-5]. The components of sustainable tourism development are identified, the main environmental problems associated with the expansion of tourism, the features of environmental aspects of tourism development in mountain tourist destinations. Ensuring the sustainable development of recreational areas is carried out through the establishment and maintenance of a balance between the preservation of natural, historical and cultural resources, economic interests and social needs and the development of tourism.

Basic concepts and principles of sustainable tourism development, characterized by environmental, economic and social aspects of its development were outlined by us [6]. A practically unresolved problem in the development of the concept of sustainable tourism development is the development and practical implementation of tools (means) to implement the principles of balance in practice. Therefore, our main goal is to analyze these issues.

2 Statement of the main material

Tourism is a constant and quite intensive user of natural resources. At the same time, the tourism industry not only makes extensive use of natural resources, but also pollutes the environment. On the other hand, the favorable ecological condition of tourist areas is considered by tourists as a separate tourist resource, which is in steady demand, especially in the period of recovery from the pandemic and the need for recovery in environmentally friendly living conditions. Negative aspects of the impact of mass tourism on the environment and tourist resources were noted in the 70's in foreign studies. The rapid development of the tourism industry has led to a high concentration of production - hotel chains appear, the construction of tourist centers begins. Investing significant funds in the development of tourism, large capital requires maximum profit in the shortest possible time. The rapid development of tourism is supported in order to ensure economic development and increase the level of currency inflows. For example, the development

* Corresponding author: alenapobigun@gmail.com

of tourism in the Mediterranean region since the 1960s and until recently illustrates the significant amounts of ecological degradation of geosystems that may occur as a result of large-scale tourism development [7]. The natural landscape and the local population were perceived only as a means to an end. Not surprisingly, the result of the growth of mass unregulated visits to recreational natural complexes was an extremely negative impact on them, as well as on the local socio-cultural environment. The wild originality of unique natural places, as well as local economies and cultural values of tourist destinations are under threat. Examples of the negative consequences that accompany excessive visits by tourists to recreational natural areas are known today in large numbers. The most convincing examples are the degradation of a number of major US national parks, the Geyser Valley in Kamchatka, recreational areas in the Alps, the accumulation of debris on Everest in Nepal (Fig.1) and the Inca Trail in South America [8]. In 1983, the famous Austrian journalist L. Lukshanderl published his book “Save the Alps! Garden on the roof of Europe in danger ", in which in popular science form outlined the main environmental problems of tourism development [9]. The degradation of natural areas for tourism development has necessitated the introduction of systematic nature protection measures in tourism practice. Since the tourism industry is mainly seasonal, the number of tourists in a given area at the height of the season is several times higher than in the "dead season". This situation leads to uneven anthropogenic pressure on ecosystems. The study of the consequences of tourism activities for ecosystems and the introduction of environmental management technologies in the practice of recreational nature has emerged as the most pressing problem of further development of tourism. However, the definition of objects of environmental research remains controversial and ambiguous.

Fig. 1. Campaign to clean up and remove rubbish from Everest left by tourists and climbers on the world's highest mountain, Nepal, March 17, 2018, photo: EPA-EFE / BIKAS KARKI.

Today, anthropogenic impact on ecosystems is characteristic of all sectors of the tourism industry and types of tourism and is observed in the vast majority of tourist destinations. It is tourist destinations of different hierarchical levels that are the objects of ecological research and are considered as natural-technogenic systems from the point of view of ecological research. The term "tourist destination" in the practice of tourism research appeared not so long ago. In foreign literature on the theory and practice of tourism, this term has been used for several decades. The most famous works of Leiper, Cooper, Fletcher, which give the definition of tourist destinations and their systematization. In a more general form, the tourist destination is the territory of arrival and location of tourists. According to N. Leiper, a tourist destination is a place of arrival of tourists and is considered as a geographical category [10].

The World Tourism Organization defines a tourist destination as follows: «A destination is a physical space in which a tourist stays for at least 24 hours. It contains tourist products such as services and attractions, as well as tourist resources within at least one day of stay. This space has physical and administrative boundaries that determine the form of its management, image and reputation, which affect its competitiveness in the tourism market». It should be noted the thorough works of domestic scientists in this field T. Tkachenko, L. Dyadechko, A. Holovchan, S. Melnychenko, Y. Leontieva, Y. Maltseva and others [11-15]. In the work of Matrishenko N.S. tourist destination is presented as a "center (territory) with all kinds of amenities, facilities and services to meet all the needs of tourists". According to him, now the destination is a geographical area that has certain boundaries, which can attract and meet the needs of a wide range of tourists [16].

In most modern interpretations, a tourist destination is considered as an economic and socio-economic system, as an object of integrated management. To do this, the tourist destination combines all the elements for the provision of tourist services. A tourist destination arises precisely as a geographical unit, as a territory, route or localized object that is a place of tourist interest ("tourist destination"), other components, such as elements of tourist infrastructure, should be considered "superstructure", gradually revealing the essence of a tourist destination in the course of evolutionary development. Thus, a tourist destination is defined as an economic and geographical category, where the basis of its operation is a territorial resource with possible problems of using nature, including environmental. Despite the rather broad and detailed interpretation of the concept of a tourist destination, the ecological aspects of its optimal functioning are ignored. A tourist destination, in the context of its balanced development, is a natural-technogenic system of tourist-recreational type, due to the specialization of tourist activity and certain factors of environmental impact that will determine its ecological safety. The structuring of natural and man-made systems of tourist destinations, their hierarchy, approaches to the systematic study of environmental aspects of their activities require further research.

At present, a scientific direction on the environmental safety of natural and natural-man-made systems of different levels has been formed. In the works of A.B. Kachynski, G.I. Rudko, S.V. Hoshovsky, V.M. Shmandiy, S.V. Rudenko, L.E. Shkitsa, B.M. Danylyshyn, V.O. Kosovtsev, Binko I.F., V.M. Shestopalov, M.S. Malovany etc. scientific and methodological approaches to ensure environmental

 https://doi.org/10.1051/e3sconf/202128009015

safety in natural and man-made natural systems, as well as applied aspects of environmental safety [17-25]. Methodological and applied mechanisms of researches of technogenic changed ecosystems and maintenance of their ecological safety are developed [26-35]. On the territory of Ukraine there are large oil fields - explored, abandoned, some and unexplored. They also pose a risk of contamination of soils, water resources, air, which in turn impairs the tourist attractiveness of tourist destinations. Therefore, the latest technological and economic methods of regulating this activity should be used to reduce the impact on the environment [36, 37].

Less studied are the issues of environmental safety research and management in the conditions of man-caused load, which is not pronounced extreme, for example, the territories of tourist destinations. The analysis of certain aspects of environmental safety in the development of the tourism industry, as part of its balanced development, engaged in A.P. Hunger, N.V. Korzh, V.I. Kutsenko, T.L. Mironova, V.V. Sharko and others [38-41]. Some scientists consider the objects of such research to be elements of infrastructure and their impact on the environment, some consider determining the ecological boundaries of activities by calculating the recreational load on the territory. Analysis of publications in recent years has identified the main impacts of tourism on the environment. Tourism can have a negative impact on local energy resources, water resources, land resources, the use of which in tourism is constantly increasing.

3 The research results

With the growth of the tourism industry, there is a direct impact on natural landscapes and changes in primary landscapes as a result of the construction of tourism infrastructure. Intensive construction of accommodation facilities, roads, airports, use of land resources as a building material for housing infrastructure leads to degradation and depletion of landscape elements, its radical change. The problem of traffic jams, insufficient number of parking spaces, a sharp increase in the cost of land have become a reality in such areas. Intensive tourism development absorbs land resources and has led to the loss of agricultural land and natural landscapes. Territories are becoming highly urbanized. The construction of marinas, breakwaters and other structures leads to changes in natural landscapes - changes in the direction and strength of currents, then - changes in the coastline and coastal erosion, which leads to the loss of beach areas. Although the pace of construction of tourist infrastructure in Ukraine is not so high, but the problems of degradation of the Black Sea coast, sampling of sand from beaches, destruction of large forests in the construction of tourist infrastructure in mountainous areas of Ukraine are very pressing environmental issues. Thus, the tourist complex "Bukovel" according to the original project occupies a considerable area: the total area for the construction of cottages and hotels: two-storey cottages - 100 hectares; hotels - 50 hectares, infrastructure of cottage - hotel complex (25-30% of housing) - 45 hectares; total area for ski slopes and lifts (at the rate of 30 to 50 m width of one track) - approximately 300 hectares; total area for water reservoirs intended for snowmaking of 60 ha of ski slopes (three reservoirs with a depth of 3 m and a volume of 16 thousand m^3 each) - 0.55 ha. The tourist complex is constantly expanding, now occupying about 822 hectares, with a total length of ski slopes of more than 100 km (Fig. 2) [42].

Fig. 2. Tourist complex "Bukovel", p. Polyanitsa.

Intensive use of water resources and their pollution is also an environmental problem of tourist destinations. Construction of hotel and entertainment complexes often leads to overload of sewer systems. Wastewater treatment plants do not always cope with large volumes of wastewater in the height of the season, wastewater is sometimes discharged into seas and lakes without treatment, negatively affecting not only flora and fauna, but also the quality of the recreational environment for vacationers.

In Ukraine, the problem of pollution of water and land resources from tourist facilities is very acute. Tourist infrastructure, especially on the coasts, is developing chaotically, without proper environmental justification. It is not uncommon for direct discharges of wastewater into the sea, the construction of hotel complexes on beaches, within water protection zones, the development of unorganized tourism on the coast in the absence of sanitary facilities. Thus, the tourist complex "Bukovel" uses groundwater for domestic and drinking water supply, production of artificial snow, which leads to the extraction of significant amounts of water from underground horizons. Sewage from small hotels and rural estates remains a problem, as the vast majority of tourist destinations do not have centralized drainage systems. Sample observations of water use in Ivano-Frankivsk region showed that the average water consumption in rural estates is about 100 liters per day, uncategorized hotels - from 120 to 300 liters per day, in star hotels - more than 300 liters per day, depending on the offers of hotels for health and recreational services (availability of swimming pools, spa treatments, etc.). These results fully confirmed the WTO data on the water consumption of hospitals: with increasing category and comfort, these figures are growing. Moreover, the indicators of water use by tourists in accommodation establishments are higher than their average consumption by the population of tourist destinations. According to approximate

https://doi.org/10.1051/e3sconf/202128009015

calculations, with an average tourist stay of 4 days, the volume of tourist water use in the region is about 2.4 million m^3.

Using of energy. Hotels and other tourist infrastructure use a lot more electricity than the average local. Thus, according to EU energy saving experts, the use of energy per 1 m^2 in a non-star hotel is 157 kWh, in a four-star hotel - already 380 kWh [43]. That is, with increasing comfort of the means of placing energy consumption increases. In many areas of tourism development, the energy system is not designed for such significant energy consumption. Thus, a significant reconstruction of the local energy supply system has been carried out in the area of the Bukovel tourist complex for uninterrupted power supply. The issue of energy supply in the tourism sector can be solved through the use of renewable energy sources, scientists have made such a justification [44-46] (Fig.3). For energy companies that are within the impact on environmental facilities, recreational areas, scientists have proposed technical solutions and new methods and means of measuring the volume of oxygen to improve the accuracy of determining the ratio of excess air during fuel combustion [47]. Also, great attention should be paid to the training of specialists in the field of energy, as well as the use of modern methods and approaches to training, the use of GIS technologies [48, 49].

Fig. 3. Vacuum solar collectors are used to heat water in the sanatorium "Carpathian Stars", Yaremche.

Air pollution and the problem of solid waste are also environmental problems of tourist destinations. The growth of the tourism industry leads to a high concentration of tourists and the corresponding infrastructure. This leads to air pollution from road, rail and air transport. For example, 60% of all air traffic in the world is directly related to tourism, so tourism is also "responsible" for air pollution. Noise pollution from transport, and sometimes from tourists themselves, is another important problem. On the other hand - air pollution is also a problem for the organizers of tourist activities, because the tourist expects from the rest areas, first of all, clean air and the absence of noise discomfort. Sources of air pollution are usually vehicles (cars) (Fig. 4). So, in the tourist complex "Bukovel" in a peak season arrival of about 900 units of motor transport is fixed daily. Atmospheric air pollution by vehicles leads to the accumulation of pollutants in soils and their subsequent migration along the food chain. In the scientific works of various authors there is work to determine the risk assessment for the population as a result of air pollution [50, 51].

Fig. 4. Dangerous car tours in the Carpathians.

For many tourist destinations there is a problem of solid waste management of tourism enterprises: the amount of waste is growing faster than the possibility of their disposal. The problem is complicated by the need to transport solid waste over long distances. Scientists have modeled the formation of solid waste within the Ivano-Frankivsk region and justified the need to take into account the increased flows of tourists in the development of roadmaps for waste management in tourist destinations [52-54].

Thus, the environmental impact of tourist destinations increases with the development of the industry and there is a need to systematize the mechanisms for implementing environmental safety within the territories of tourism. We have analyzed and summarized information on the application of various measures and mechanisms to ensure the environmental safety of natural and man-made systems. We propose to classify them into regulatory, economic, controlling and voluntary mechanisms for ensuring the environmental safety of tourist destinations (Fig. 5).

Regulatory tools make it possible to reduce the impact on destinations from tourism by regulating the capacity of the territory, setting limits and limits on the activities of enterprises providing services to tourists, through environmental impact assessment of tourism, environmental monitoring and sustainability of territories. Regulation of the number of tourists on the territory is an important factor in the balanced development of tourist areas. Territorial communities and environmental structures in the territories of which tourism is developing can regulate the flow of tourists, offering alternative routes and optimizing tourist flows quantitatively. This factor must be taken into account when planning recreational settlements. The system of monitoring potential impacts on the territory is a necessary tool for monitoring the environmental parameters of pollution and indicators - indicators of balanced development of territories. In the system of observations at the first stage it is necessary to carry out inventory of the basic recreational resources, definition of objects of monitoring, a choice of estimation parameters, a mode of supervision.

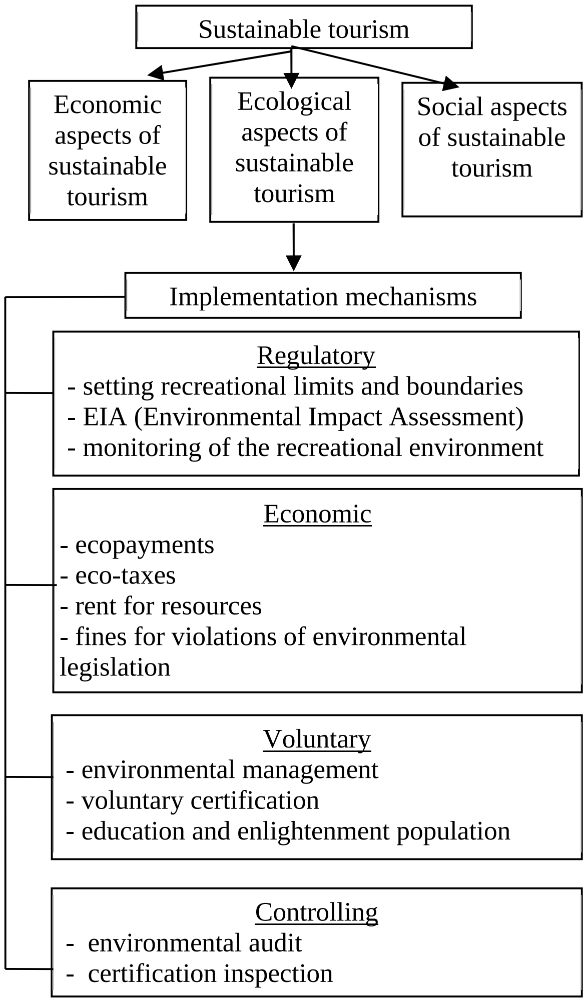

Fig. 5. Mechanisms for ensuring the environmental safety of tourist destinations.

In the process of forecasting the state of the recreational environment determine possible negative trends in its development in various aspects, such as increasing the functional hazard of tourist and recreational equipment, deteriorating ecological condition of tourist destinations, reducing the attractiveness of tourist facilities, etc. Together, these processes can lead to the degradation of tourist destinations, reduce the flow of tourists. The results of forecasting can be a factual basis for the development of measures to manage the recreational environment. Managment is considered as practical activities in the field of regulation of recreational systems in accordance with the needs of the economy and tourists on the basis of objective laws of nature and socio-economic development. The success of management measures is determined by the effective functioning of tourist destinations, namely the positive dynamics of the tourism industry and related industries, the optimal load of the recreational environment by vacationers, favorable environmental conditions of tourist destinations and safe use of recreational resources. Thus, this monitoring system fits into the traditional framework of monitoring concepts.

Setting limits on the environmental impact of tourism facilities is seen as an effective mechanism for ensuring the environmental safety of tourist destinations. Compliance with environmental standards is the most important component of the mechanisms for implementing the principles of balanced tourism. Environmental standards are uniform and mandatory for all objects of this type and level of the system of norms and requirements for the environment.

The main economic mechanisms for ensuring the environmental safety of tourist destinations are financial incentives, monetary rewards, financial support for projects aimed at implementing the principles of balanced tourism, balanced tax policy and procedures for subsidizing balanced tourism projects. Tourist eco-taxes and payments are taxes paid by tourists for the ecological needs of territories. This practice is common in the most environmentally vulnerable tourist destinations in the world.

The main control mechanisms for ensuring the environmental safety of tourist destinations are to implement actions to control the activities of tourism entities in the field of environmental safety of tourist destinations. Conducting an environmental audit is an important management tool, which is a systematic, documented periodic and objective assessment of the organization's compliance with the management system, equipment for environmental safety and environmental policy of the enterprise.

Certification is a process of assessment and monitoring that confirms in writing that a business, product, process, service or management system meets certain requirements. This process is important in enterprises of different directions [55]. In the practice of environmental certification of accommodation establishments, there are about 30 eco-labeling systems. In Ukraine, a method of voluntary environmental certification of rural tourism homes "Zelena sadyba" has been developed.

The main additional mechanisms to ensure the environmental safety of tourist destinations include the introduction of environmental management in the structure of general management, marketing and demarketing, training of tourists and locals. Professional environmental management in the tourism industry, especially hospitality, such as energy saving measures, reducing water consumption, waste minimization, the use of environmentally friendly materials can reduce the environmental impact of tourism development. Training of tourists and locals can take place various forms. This is the implementation of educational programs, social advertising, printed materials, volunteer work, etc. This activity becomes especially relevant in the process of organizing ecological tours, visiting natural, nature reserves.

4 Conclusions

Thus, the main problem in the development of the concept of sustainable development of tourism is the development and practical implementation of tools (means) to implement the principles of balance in practice. Ensuring the environmental safety of tourist destinations is one of the main priorities for sustainable tourism development.

Favorable environmental situation within tourist destinations is considered by tourism experts as an equivalent factor in the development of the tourism industry. Mechanisms for ensuring the ecological safety of tourist destinations are proposed, the use of which will allow to implement the ecological component of sustainable tourism development. Research on the effects of man-made load on the ecosystems of tourist destinations is a promising scientific field in the field of environmental safety.

Abstract. Theme of the paper is the solution of flooding geomodels creation for Dniester river basin territory, which uses contact and remote measurements. Natural and anthropogenic factors causing groundwater level rising were analyzed for localization of flooded zones and forecasting of geometric characteristics. Geographic information systems for researched area include the spatial binding of the hydrological elements and observation points, digital model of relief preparation, basin allocation catchment, flooded areas modeling. Structural features include the size and shape of object, brightness disposal within the object, image texture, some others. Possibility of available remote sensing data use allows reducing temporal and economic cost for conducting additional ground measurements for possible flooded areas determining. These methods of geomodels creation are realized for the territory of Dniester Canyon, the hydrogeologic feature of which is connected to the Upper Cretaceous horizon and groundwater.

1 Introduction

This research objective is to create cartographic models of potential flooded zones in the Dniester river basin in Ukraine. Environmental researches, particularly in the context of anthropogenic influence, show negative dynamics of flood events statistical frequency. In order to make well-timed decisions of possible negative consequences preventing or eliminating, remote sensing methods are being actively used. Development of new and improving the existing geomodels creating methods, just as potential flood zones definition, is possible on the basis of remote and contact measurements comprehensive using. It also requires considering hydrogeological conditions diversity and geographical conditions of the researched area [1-3].

Every year the problem of new and new territories groundwater flood is growing. It leads to sanitary and epidemiological deterioration, to groundwater and soil chemical composition changing, to corrosion activity increasing which relate to engineering structures foundation, to dangerous geological events activation, etc.

Experimental researches of anthropogenic factors that were associated with flood in the Dniester river basin are based on expert assessment and information technology methods. Geomorphological researches, geological researches of Dniester canyon, Dniester terrace formation history was made by O. Adamenko, A. Bohutskiy, A. Yatshishin, S. Rudnitskiy, E. Romer. Current environmental situation researchers in the territory of Dniester anti-flood area are considered by Y. Adamenko, D. Zorin, Y. Semchuk and some other scientists. Scientometric analysis results showed a number of environmental problems in this area which need to solve.

2 Results

The aim of the research is to solve a scientific and practical task of potential flood geomodels creation substantiation in Dniester river basin, which has to base on aerospace and ground measurements.

Prevention of emergencies associated with flood in Dniester river basin requires continuous monitoring with analysis and assessment of received data. Flooded areas detection is carried out using remote and contact methods.

The ecological danger of flooding occurs in such landscapes as river valleys terraced bottoms. It takes the form of destructive coastal erosion, while high water disasters take place in foothills within the boundaries of floodplains. Among geomorphological processes, most hazardous for the environment, are landslides. This phenomenon is wide-spread in areas of erosion-shifting interfluve and hilly lowlands, landslides and shoals – in mid-high mountains with stiff slopes [4-7].

Chemical pollution of the territory does not have a strong coherence with landscape type; it tends to local sources of influence, around which anthropogenic geochemical anomalies are formed. Totally, there are nearly 18 man-made anomalies in the Dniester Canyon which occupy southern boundary of Ternopil region.

Contact methods allow accurate measurements of the groundwater depth, but some errors can occur in the process their boundaries establishment [8-13]. These methods also require large quantity of material and labor resources.

In the process of degree of risk for the geomodels hierarchical structure formation determining, interval estimates method using helps to make operational decisions

 https://doi.org/10.1051/e3sconf/202128009016

to prevent consequences of dangerous engineering-geological processes in uncertain conditions. This method requires establishing dependencies between model parameters that characterize various possible situations of researched areas, using expert assessment and statistical analysis.

This way contributes to increase the accuracy of flooded zones localization with different degrees of danger [17,18].

Geographic information systems for researched area include the spatial binding of the hydrological elements and observation points, digital model of relief preparation, basin allocation catchment, flooded areas modelling (Fig. 1).

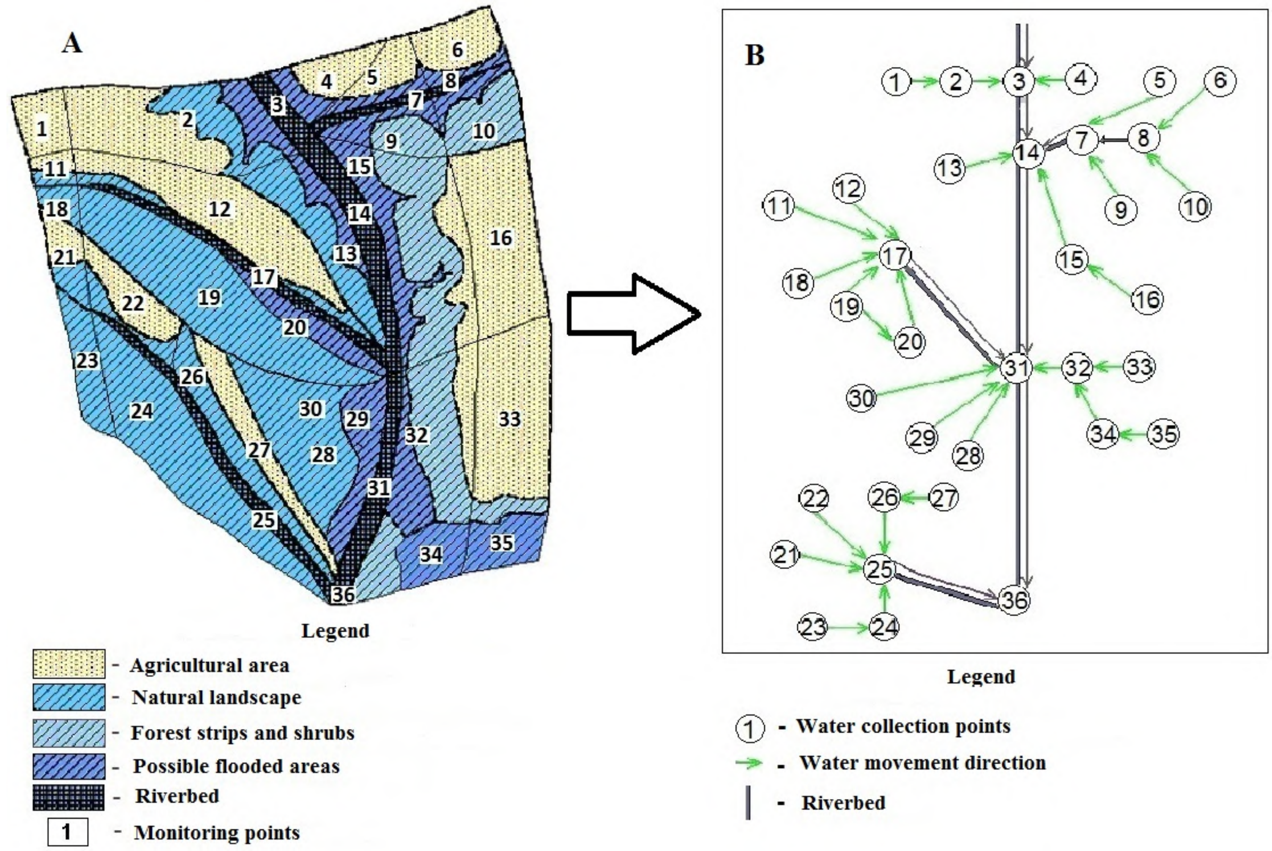

Fig. 1. Cartographic and graph model of the flood on Dniester river segment in rainy weather: A) Map of flooded territory; B) Graph representation of the model.

Proposed flood mapping representation and graph model representation of the Dniester region are basing on aerospace and ground survey using, which include data analysis for obtaining topographical or special maps and digital relief model construction.

Constructed graph shows the points of research and catchment area branching peculiarities on the territory. The final aim of proposed methodology is to assess and to consider actions of flood and deformation accidents struggling [14-16].

Natural and anthropogenic factors leading to groundwater level rise were adjusted for flooded zones localization and geometric characteristics dynamics forecasting. Possible unfavorable processes in flooded zones were established factored in the characteristics of the territory. Four flood categories depending on groundwater lever occurrence, causing factors and possible consequences were separated. Categories I and II accords to areas with groundwater depth is less than 2.5 m, where dangerous phenomena occur. Category III accords to possible flooded areas with a groundwater depth from 2.5 to 4 m, where tendency to groundwater level rise can be noticed. Areas in category IV cannot be flooded, because there are no predictions for flooding if groundwater level is deeper than 4 m.

Cosmobioindication method (by G. Krasovskiy) enables to make monitoring of waterlogged lands. This method [19-21] is based on vegetation conditions (determined by vegetation indexes measurement) depending on land waterlog degree. The application of this method is limited to unpowered soybean soils.

It is necessary to assess possible risk of groundwater shallow occurrence to determine degree of danger for researched territory. Creation of new and improving existing methods of geomodel developing for potential flooded areas is possible only after comprehensive remote sensing results and ground measurements using. Also requirement is to take hydrogeologic conditions diversity and geographical specific of the area into account.

Fig. 2 shows the structural scheme to develop geomodel for probable flooded zones according to danger degree.

There are four stages to make cartographic model with different flooding probabilities. At the first stage, it is necessary to create cartographic models of probable flooded areas based on the rules of fuzzy production system. Also SRTM (radar topographic survey) data and available ground measurements data have to be used. [22,23].

At the next stage, thematic decoding of aerospace images is made in order to identify geomorphologic

 https://doi.org/10.1051/e3sconf/202128009016

elements and potential sources of anthropogenic impact for developing of cartographical models of natural and man-made flood based on only classification characteristics assessment scale. If it is necessary, photogrammetric image processing is executed. Third stage is to specify the flooding geomodel through overlay operations on cartographic models built on the base fuzzy production system rules and interval scale of evaluation. At the final stage, a complex hierarchical geomodel of probable flooding zones (based on danger degree) is created. It is made through specified geomodel and anthropogenic flood overlaying.
